A survey of flexibility training protocols and hamstring strains in professional football clubs in England

B Dadebo, J White, K P George

Objective: To investigate the relation between current flexibility training protocols, including stretching, and hamstring strain rates (HSRs) in English professional football clubs.

Method: Questionnaire based data on flexibility training methods and HSRs were collected from 30 English professional football clubs in the four divisions during the 1998/1999 season. Data were coded and analysed using cross tabulation, correlation, and multiple regression.

Results: Flexibility training protocols were characterised by wide variability, with static stretching the most popular technique used. Hamstring strains represented 11% of all injuries and one third of all muscle strains. About 14% of hamstring strains were reinjuries. HSRs were highest in the Premier (13.3 (9.4)/1000 hours) with the lowest rates in Division 2 (7.8 (2.9)/1000 hours); values are mean (SD). Most (97%) hamstring strains were grade I and II, two thirds of which occurred late during training/matches. Forwards were injured most often. Use of the standard stretching protocol (SSP) was the only factor significantly related to HSR (r = −0.45, p = 0.031) in the correlation analysis, suggesting that the more SSP is used, the lower the HSR. About 80% of HSR variability was accounted for by stretching holding time (SHT), SSP, and stretching technique (STE) in the multiple regression equation: HSR = 37.79 − (0.33SHT − 10.05SSP + 2.24SSTE) / 2.34. SHT (negatively correlated with HSR) was the single highest predictor, and accounted for 30% of HSR variability, and an additional 40% in combination with SSP.

Conclusions: Flexibility training protocols in the professional clubs were variable and appeared to depend on staffing expertise. Hamstring stretching was the most important training factor associated with HSR. The use of SSP, STH, and STE are probably involved in a complex synergism which may reduce hamstring strains. Modification of current training patterns, especially stretching protocols, may reduce HSRs in professional footballers.
flexibility training protocols and injury rates in professional footballers. The purpose of this study therefore was to determine the current protocols of flexibility training, including stretching protocols, in the English professional football clubs and whether any relation exists with hamstring strain rates (HSRs).

**METHODS**

This study was conducted as a follow up to one involving 30 professional football clubs. However, only 20 of the original clubs responded, hence a further 16 clubs selected randomly from all four divisions were invited to participate. Of these, 10 clubs responded. In all, 30 out of 46 clubs took part in this study, eight from the Premiership, 10 from Division 1, and six each from Divisions 2 and 3. Team doctors, physiotherapists, managers/coaches, and fitness trainers who work with the first teams of their respective clubs provided information based on the 1998/99 soccer season. Self administered questionnaires with a mixture of open ended and closed questions were mailed to staff of clubs who agreed to participate in the study. The questionnaire was designed with the help of the Division of Public Health Medicine and Epidemiology (University of Nottingham), and was based on a review of the relevant literature in the area of study. The questionnaire contained clear definitions of words such as injury and reinjury, and classification of hamstring strains, etc to facilitate completion. It also provided guidelines for completion of specific sections by the most appropriate support staff.

Pertinent areas of interest in relation to the study included: staffing complement, demands of the football year, fitness training procedures, warm up and warm down procedures, flexibility training procedures, and injury information. In this study, injury refers to “a physical impairment received during a competitive match or training session which prevented a player from being available for selection for the next competitive game”. Hamstring reinjury in this survey refers to a second injury occurring at the same site during the 1998/99 football season. Hamstring strains were classified as grade 1 (minor injury with normal, but painful contraction), II (moderate, partial tear with abnormal contraction), and III (minor injury with normal, but painful contraction), and diagnosed by the team doctors. Clubs that took part in this survey used on average two doctors working full time or part time. About 45% of these doctors have MSc/Diploma Sports Medicine qualification, the others being orthopaedic surgeons (14%), general practitioners (17%), and osteopaths (24%). On average, the head doctor of the clubs had experience in sports medicine ranging from 6.5 years (Division 3) to 9.8 years (Premiership). The timing of hamstring strain incidence was also noted as early, mid, and late onset during the first, middle, or last third of matches or training sessions respectively. In this survey certain terms were coded for simplicity, SSP (standard stretching protocol), STE (stretching technique employed), SHT (static stretching holding time), and HSF (hamstring stretching frequency or repetitions per session). STE referred to static, PNF, or ballistic stretching. In static stretching, the muscle is moved slowly through its range of motion and held for a length of time, whereas ballistic involves jerky/bouncing movements rapidly taking the muscle through its range of motion. PNF referred to partner assisted slow movement of the muscle through its range of motion with a concomitant combination of alternating contraction and reflex relaxation of both agonist and antagonist groups. SSP in this survey referred to the use of either the static or PNF stretching technique, preceded by a warm up session, and holding the static stretch for 15–30 seconds. Accordingly flexibility training protocols in the survey implies stretching exercises used for the purposes of enhancing flexibility of the hamstring muscles together with warm up and warm down activities.

Supervision of flexibility training was the responsibility of the sports scientists and fitness trainers with support from coaches and physiotherapists. However, as sports scientists and fitness trainers were employed mainly by the Premiership clubs, the head physiotherapists and coaches in the lower divisions often led and supervised flexibility training. The minimum average experience of the head physiotherapists was 9.8 years. Over 90% of full time physiotherapists employed have chartered and/or FA Diploma in Physiotherapy as qualification.

The proposed questionnaire was piloted with three English professional clubs, with doctors, physiotherapists, and coaches who had experience working with first teams as respondents. These three clubs did not take part in the final study, although appropriate amendments were made to obtain the final questionnaire based on the responses and comments received. The clubs that agreed to participate in the main study were mailed questionnaires with self addressed, stamped envelopes. Clubs were assured of the confidentiality with which responses would be treated. Reminders were sent to 23 clubs who did not respond within two weeks, and new questionnaires were sent together with the second reminders to non-responding clubs within four weeks. Follow up phone calls were used in retrieving records or the fact that the records were simply not available.

Total muscle and hamstring strain rates were calculated from information contained in the returned questionnaires based on the total number of matches (each match lasting 90 minutes) and training sessions (each session lasting 120 minutes) completed during the season. The total number of muscle and hamstring strains reported was divided by the total time of exposure to match playing and training during the season and expressed per 1000 hours. The data were screened for variance of individual data, including tests for skewness and kurtosis. Four reports on frequency of hamstring stretching from three Division 1 clubs and one Division 3 club were considered outliers and excluded from the analysis. The distribution of hamstring strains, muscle strains, and total injuries were cross tabulated, and the relation with training practices assessed using Pearson’s (interval data) or Spearman’s rank order (nominal data) correlation and then stepwise multiple regression. One-way analysis of variance was used to determine the main and interaction effects of stretching factors on HSR after the tests of association. p<0.05 was considered significant (SPSS).

**RESULTS**

Thirty clubs returned the study questionnaires, which consisted of six sections; however, only 19 clubs completed all six sections. Section 6 of the questionnaire had a series of questions on injury information, the completion of which required retrieving stored information. Therefore the ability to complete this section depended on record keeping and storage of information. Thus section 6 was the least completely completed section, with 23 respondents. Although seven clubs failed to complete section 6 fully, the total number of responses about the incidence of hamstring strains for example was 27. Overall, the total number of responses declined for questions that demanded details of...
distribution/timing of hamstring strains or subclassification of specific training programmes. This led to differential totals included in the respective analyses conducted: 21 responses for flexibility training compared with 27 for hamstring strains or 30 for number of physiotherapists employed. Again, although the number of responses about hamstring strains was 27, data on hamstring strain rates/1000 hours could only be calculated for 23 clubs because some clubs failed to provide information on their training duration.

### Staffing complement

Clubs in the Premiership employed more support staff than all other divisions (table 1). Most Premiership clubs employed at least two doctors compared with one for all other divisions. Most clubs in all divisions employed at least two physiotherapists, with the widest range in the Premiership.2–7 Sports scientists and fitness trainers were only sporadically employed, with at least one sports scientist exclusively employed in the Premiership (table 1). The number of players employed in the professional football league increased from Division 2 and 3 clubs to a maximum in the Premiership, which probably accounted for the additional support staff needed.

### Training patterns

The training modalities used by the professional clubs included endurance training, strength/resistance training, and flexibility training. The training patterns were characterised by very wide inter/intradivision variability (table 2). The pattern of training modalities could not be reported by some of the clubs (table 2), explaining the differences in response numbers. However, on average, clubs in Divisions 1 and 2 seemed to devote more time per week to endurance training, whereas the Premiership clubs devoted slightly less time, and Division 3 clubs devoted the least time.

Strength/resistance training was also characterised by wide inter/intradivision variability, although half of Division 2 and 3 clubs failed to report, and two Premiership clubs and one Division 1 club also failed to report. The Premiership spent more time on strength/resistance training, whereas only about half this time was devoted by Division 3 clubs, with clubs in Division 1 and 2 spending about two thirds of this time on strength/resistance training.

Unlike with endurance and strength/resistance training where some responses were similar, flexibility training exhibited distinct patterns for each division. The most time spent on flexibility training per week was by Division 1 clubs, followed by the Premiership clubs, then Division 2, and the least by Division 3. This pattern in flexibility training was similar to the trend in total training times for all three modalities.

The Premiership clubs devoted almost 40% of total training time to flexibility training, with about 30% on endurance and 30% on strength/resistance training. Division 3 clubs also exhibited similar training protocol distributions. In Division 1, nearly 50% of training time was devoted to flexibility training, with about 30% and 20% to endurance and strength/resistance training respectively. Division 2 clubs used the least flexibility training, representing a third of total training time a week, while almost 40% of time was used for endurance training.

### Warm up and warm down procedures

All clubs reported using warm up protocols before training sessions and matches. Table 3 summarises the characteristics of warm up and warm down protocols. Whereas almost two thirds of all clubs used mainly active warm up, over two thirds of Division 2 clubs used both active and passive warm up protocols. In addition, five out of six Division 2 clubs and seven out of 10 Division 1 clubs reported using warm down protocols both after training and after matches. In the Premiership and Division 3 clubs, the use of warm down protocols after a match fell to half (four out of eight Premiership clubs) and a third (two out of six Division 3 clubs) respectively compared with its use after training. There were no differences in the duration of warm up use across all divisions, with warm ups lasting 22–25 minutes, although Division 2 clubs spent less time on warm down compared with the other divisions. Overall Division 3 clubs used warm down protocols the least, and Division 2 clubs the most. Stretching before warm up was not popular in all divisions except Division 2 where half (three out of six) used stretching before warming up. However, seven out of eight Premiership clubs stretched both during and after warm up, with seven out of 10 Division 1 and four out of six Division 3 clubs doing likewise.

### Hamstring stretching

Static stretching was reported as the most popular stretching technique used among all clubs in this study. In most cases,

*Active warm up involves gaining body temperature through one’s own physical activity. †Passive warm up involves gaining body temperature through the use of an external heat source (application of hot material or use of additional clothing to retain heat).

HSRs and training factors
The use of an SSP was the only training factor that correlated significantly and negatively with HSR (r = −0.53, p = 0.01; table 6), suggesting that the use of SSPs is associated with lower HSR.
In addition, there was a significant interactive effect between SHT and STE (analysis of variance; \( F = 7.1, p = 0.04 \)) without significant individual main effects (SHT: \( F = 2.8, p = 0.71 \); STE: \( F = 1.7, p = 0.3 \)) (table 7).

**Prediction of HSR**

Stepwise multiple regression analysis using the specific training factors as independent variables indicated that stretching was the most important factor associated with HSR (table 8). SHT was the single most important predictor, accounting for nearly 30% of variability of HSR (\( r^2 = 0.29 \)). SSP in combination with SHT adds 40% to the variability of training. \( 41 \)

**DISCUSSION**

The flexibility training protocols of 30 English professional football clubs during the 1998/99 season were studied, with the aim of identifying any training factors that may be associated with HSR. There were no differences in training protocols within or between divisions that could be attributed to the fact that people of different backgrounds and experience are recruited to manage and supervise training. Moreover, the desired impact of sports scientists/fitness trainers is probably not being achieved because of the low numbers involved in professional football in England. Furthermore, there are no clear guidelines on the number and qualifications of staff to be employed by clubs. \( 42 \)

Appropriate stretching protocols are thought to increase flexibility, but the optimum level of flexibility to prevent injury is not clear and may vary between muscle groups and probably sports. There is the general perception that the concept of specific training according to individual needs is familiar to coaches/trainers and players. Consequently it has generally been assumed that coaches/trainers and players know how to prepare in terms of stretching and flexibility training; \( 41 \)

This study shows that hamstring SHT, the use of SSPs, and the type of STE were the most important training factors affecting HSR. As most clubs used and adhered to SSPs, it could be argued that it is what the players actually do in practice, particularly the STE and SHT, that determines how much benefit is obtained in terms of prevention of HSRs. What is apparent is that the stretching protocols currently used by professional footballers are not necessarily detrimental, but may only be beneficial when the STEs and SHTs are appropriate. We found no significantly different HSRs among the divisions. This may be because the numbers were too small or the stretching protocols used by the clubs were similar and not sufficient to promote the desired benefits. Current recommendations are a combination of static and PNF techniques instead of ballistic stretching; \( 43 \); an SHT of

\[
\text{HSR} = 37.79 - (0.33 \text{SHT} + 10.05 \text{SSP} + 2.24 \text{STE}) \pm 2.34
\]

95% confidence intervals are shown in parentheses. N represents the number of clubs in a particular division participating in the study. n represents the number of clubs that responded to the questionnaire on the stated component of injury, HSR, Hamstring strain rate; MSR, muscle strain rate; TIR, Total injury rate.

The model components include: 1, One predictor: (constant), hamstring stretching holding time (SHT) (seconds); 2, two predictors: (constant), SHT (seconds) and use of standard stretching protocol (SSP); 3, three predictors: (constant), SHT (seconds), SSP, and stretching technique employed STE. (1) SHT indicates the extent to which the stretching holding time used influences the tendency for injury prevention; (2) SSP indicates the extent to which the use of standard stretching protocols used influences the tendency for injury prevention; (3) STE indicates which stretching techniques employed influence the tendency for injury prevention.

www.bjsportmed.com
15–30 seconds is also advocated. Up to four repetitions per stretching session is thought to be adequate. In a more recent study, 15 seconds holding time was found to be more effective in enhancing active flexibility but not passive flexibility compared with five seconds. These findings suggest that gains in flexibility may be linearly related to SHTs up to 30 seconds. In our study, but for the wide intra and inter division variability, SHTs would otherwise be within acceptable ranges. Consistency in the use of such SHTs in protocols using the sound techniques may hold the key for benefits of stretching in injury prevention. Arguments based on the basic scientific evidence that stretching could cause injury have been suggested, appear laudable, and have not been disrupted. However, if investigations into stretching fail to consider consistent use of appropriate STEs and SHTs and their interaction with other training factors, the results are unlikely to reveal any relation with injury. Authors of such studies are likely to report conflicting findings, and this raises concern about experimental designs, whether randomised clinical trials or cohort, and their interpretations. In a previous review article, the only studies showing a link between HSR and stretching were those that used multiple intervention. In the present study, the simple relation between HSR and stretching could not be established by correlation analysis, but only by stepwise multiple regression analysis. Moreover SHT and STE showed no single main effects, but rather a significant interaction effect on HSR. This therefore implies that stretching is only beneficial if held for an optimal length of time—for example, 15–30 seconds—as suggested by the literature. These findings indicate that the causes of injury in general, and hamstring strains in particular, are likely to be complex, interactive, and multifactorial involving flexibility, strength, warm up, and fatigue. It has been suggested that stretching must therefore interact with other training factors to have an injury preventing effect. Our findings clearly suggest that the current stretching practices of professional footballers are not detrimental, and an improvement in the quality and consistency of use of more appropriate stretching may possibly further reduce HSR.

In this study, muscle and hamstring strains accounted for 33% and 11% of all injuries respectively. This compares with another study of four English professional football clubs, in which 41% of injuries were reported as muscle strains, and a study of Australian rules football, in which hamstring strains represented 13% of all injuries. Hamstring strains occur when strong concentric quadriceps contractions generate forces that the eccentric strength of the hamstrings cannot withstand. They are therefore prevalent in sports requiring sudden bursts of speed. In the present study, forwards, who “take off” more often with sudden bursts of speed, had the highest relative risk (16:1) with respect to goalkeepers compared with defenders (12:1) and midfielders (11:1). Even though it has been reported that midfielders do more running and are thus more prone to injury, the literature suggests that high instantaneous speed demands are associated with hamstring strains. Our study supports such a mechanism. In fact, it has been reported that hamstring strains are more common in faster athletes. In this survey, goalkeepers had the lowest HSRs. This can be explained by the relatively rare demand for sudden bursts of speed in this position rather than having the greatest flexibility. Grade III hamstring strains were rare, and most of the few that occurred were in the Premiership. Tiredness has been suggested to contribute to hamstring strains. The fact that most hamstring strains in our study occurred late on during activity supports this. In all the 122 hamstring strains that were timed, 74 occurred late during the activity (training or matches), 26 occurred mid-activity, and the remaining 22 occurred during early activity.

In this survey, reinjuries represented 14% of hamstring strains and appeared to increase the lower the division: from 9% in the Premiership to 21% in Division 3. In Australian Rules football, hamstring reinjuries have been reported as 34%, more than double the average rate in all divisions of the football league in England. Apart from individual susceptibility, inadequate rehabilitation and premature return to competition have been mentioned as reasons for reinjury. This survey was a follow up to a previous study which investigated the use of physical profiling for guiding return to unrestricted training after injury, and 20 clubs out of the 30 in this survey took part in that study. It is therefore not surprising to note the relatively low rates of hamstring reinjury after the increased awareness in benchmarking to guide return to training after injury. Another reason could be the availability of sports scientists and physiotherapists who are responsible for rehabilitation of injured players. This survey shows that the number of physiotherapists and sports scientists decrease from the Premiership to the lower divisions, and this may explain the trend in hamstring reinjury rates.

The major limitation of this study is that not all clubs in the football league took part, which was further compounded by the failure of some clubs to complete certain sections of the questionnaire, particularly those dealing with injury types and classifications. This may simply mean that such fine details of injury information are not routinely recorded. Another limitation is that training protocols were investigated in clubs and not in individual players. A study of individual players and their training practices may produce more realistic results. Similarly, although hamstring strains and the various grades were clearly defined, diagnosis and classification could only be assumed to be correct, given the experience of doctors and physiotherapists employed by the football clubs. However, there may be slight disparities in diagnosis and classification. Despite these limitations, however, the study shows the contribution of stretching to hamstring strains in professional footballers in England, and a modification of current training protocols is suggested. Further research is needed to determine ideal stretching protocols, particularly the most appropriate techniques and holding times for the prevention of hamstring strains.

In conclusion, this study suggests a relation between flexibility training protocols in professional footballers in England and HSR, and that STE and SHT are the most important components of a standard protocol that may have potential for prevention of hamstring strains.

Sodium ingestion and the prevention of hyponatraemia during exercise

The study of Twerendold et al.8 is important for a number of reasons, not all of which may have been emphasised sufficiently by the authors. Firstly, it confirms that a rate of fluid intake of 1000 ml/h is too high for a group of female runners running at ~ 10 km/h and who would therefore complete a 42 km marathon in about 4.25 hours. As the athletes drank 4 litres and gained 2 kg during the trial, their average rate of weight loss (as opposed to sweat rate) was about 500 ml/h. As not all of the weight lost during exercise is sweat and as much as 1–3 kg of this weight loss may result from fuel and water losses that do not contribute to dehydration,9,10 the absolute maximum rate at which these athletes should have ingested fluid during exercise was probably even less than 500 ml/h. This is substantially less than the drinking guidelines of the American College of Sports Medicine11,12 and the Gatorade Sports Science Institute13,14 and the exact rate of sodium ingestion. This indeed is an entirely different question, which cannot be answered with the study design chosen by these authors.

For example, the presence of a control group who drank according to the dictates of thirst (“ad libitum”) and not according to the guidelines of influential sports medical15 and commercial organisations, so that they may be less prone to overdrink and so to gain weight during exercise, would have established that athletes who lose more than 1–3 kg during exercise do not develop hyponatraemic encephalopathy16 even though they are both dehydrated and sodium deficient. Rather, they are more likely to finish such races with raised serum sodium concentrations.17–19 I would rather argue that a fundamental feature of all prospective trials that aim to evaluate a novel intervention such as the role of sodium ingestion in the prevention of hyponatraemia during exercise should be to compare the new intervention with the currently established best practice.

As the currently established best practice is not to ingest fluid at such high rates that weight is gained during exercise, because this practice can produce a fatal outcome,20 so this study design should, in retrospect, not have been sanctioned. Rather, the control group in the study should have ingested fluid according to guidelines based on the strongest body of current information. It is, for obvious reasons, my biased opinion that the guidelines that come closest to a defendable evidence base are those that have been recently accepted by the United States Track and Field and the International Marathon Medical Interests.21,22

Fortunately the data of Twerendold et al.8 do allow some calculations to estimate the likely value of the extra sodium that was ingested by two of their groups. Thus, the athletes in their study lost 4.6 kg—about 1.28 mmol/l—of sodium hypotonic encephalopathy,23,24 it is not immediately clear why the authors chose such high rates of fluid intake in these athletes. Except, perhaps, if they wished to “prove” the value of sodium ingestion during exercise. I note, for example, that the study was funded by a commercial company that, I am informed, markets a sports drink containing sodium chloride.

For it seems highly probable that if athletes overdrink so that they retain fluid and gain weight, then the extent to which their serum sodium concentration falls will be influenced, albeit to a quite limited extent, by the sodium content of the ingested fluids. This indeed was shown by the results of this study. But whether that finding has relevance to the sodium requirements of athletes who are specifically advised not to overdrink during exercise to ensure they do not develop hyponatraemic encephalopathy25 is an entirely different question, which cannot be answered with the study design chosen by these authors.

Unfortunately, the vital importance of these small changes in ECF volume in determining whether hyponatraemic encephalopathy will develop in those who overdrink during exercise26 cannot be ignored. This indeed was shown by the results of this study. But whether that finding has relevance to the sweat [Na+] of 12.42 mmol/l in the W and H groups respectively (as their total sweat losses were ~2 litres in each group).

The clear paradox identified by the calculation in table 1 is that (a) the total Na+ loss apparently increases with increased Na+ intake and (b) the estimated Na+ loss in the group who ingested only water during the race (W) is less than one third of that in the group who ingested the most Na+ (H) during the race.

As these calculations are based on two real measurements (body weight changes and changes in plasma [Na+]), this apparently ludicrous conclusion can only be explained if (a) Na+ ingestion during exercise increases whole body Na+ losses in sweat and urine or (b) the estimated ECF volume in the W group after exercise is less than the value calculated. That is, specifically in the W group, the ECF volume contracted despite an increase in TBW of 1.9 litres. Indeed, this response is to be expected. There is consistent evidence that the response of the ECF and the intracellular fluid (ICF) volumes to fluid ingestion during prolonged exercise are influenced by the Na+ content of the ingested fluid27,28 so that the ICF volume is likely to be expanded.29

That they did not have such low plasma [Na+] indicates the importance of small changes in ECF volume (in this case only 450 ml or ~3% of the total ECF volume) in determining the extent to which the serum [Na+] changes during prolonged exercise in which subjects both sweat and ingest fluid to excess.30

Unfortunately, the vital importance of these small changes in ECF volume in determining whether hyponatraemic encephalopathy will develop in those who overdrink during exercise26 cannot be ignored. This indeed was shown by the results of this study. But whether that finding has relevance to the
H, High sodium intake; L, low sodium intake; W, water during exercise.

*Based on 25% of mean body weight of 57.7 kg for the total group of runners. Weights for different groups were not reported.

†From table 2 of Twerenbold et al.: to convert mg sodium (table 2) into mmol sodium, divide by the molecular weight of sodium (22.99).

**BOOK REVIEWS**

**Tennis**

It is widely recognised that each sport has its own unique demands and injuries. Therefore the IOC, IFF, ATP, WTA, and Society for Tennis Medicine and Science should be congratulated on producing, in this publication, a comprehensive overview of tennis sports medicine. Together they have assembled an impressive array of experts in this field to write succinct and relevant chapters.

Every aspect of tennis is covered to cater for a broad range of readers, including players themselves. Some areas are covered in a high level of technical detail to please the biomechanists, in particular. However, some of the sports medicine is basic in concept and lacking significant evidence based validation.

Nevertheless, I would highly recommend this book to any health professional who treats a large number of tennis players. Most chapters provide a useful link between common sports medicine problems and their occurrence in tennis, including conditions that are unique to this sport. At times, some authors are somewhat optimistic with their view of recovery time from surgery—for example, three weeks for arthroscopic debriement of the infrapatellar fat pad.

Overall it is well presented with relevant and useful photographs and diagrams to aid the reader, and each chapter gives a list of further recommended reading. Unfortunately the book does not provide an answer to where 14 million tennis balls go, imported each year into Australia, as discussed by the editor recently!

**Rating**

- Presentation 16/20
- Comprehensiveness 16/20
- Readability 16/20
- Relevance 16/20
- Evidence basis 16/20
- Total 75/100

**Dying to win**

Dying to win gives an eye opening account of the extent to which drugs play a major role in sport. Doping is not new and has been used in sport since ancient Olympic times; it is just that drug use in modern times is at such a level of sophistication, it is now an industry in its own right. The book describes the privileged position sport holds in society, having appeal for both the participant and the spectator. This has led to the massive media interest, commercialisation, professionalism, and governmental regulation and manipulation. Economic pressure in the industrialised world and governmental propaganda in the former East Germany, and more recently China, paved the way for increasing pharmaceutical intervention in sport. With the fall of the GDR, the world saw for the first time what it had long suspected, the extent of systematic doping on a State run basis, and the most interesting fact is that the East Germans kept excellent records! Further, the book takes a look at the next big issue surrounding drugs in sport—genetic engineering.

Dying to win does not just describe the evolution of doping. It explains the complex relation between anti-doping policy, implementation of those policies, and the role of governments, the IOC, and international and national sporting organisations. With the ever increasing involvement of the legal profession, a vicious circle occurs: it becomes too costly for sporting organisations to fight court battles, with their reliance on Government funding depending on results and punishments set in accordance with what will stand up in courts. This all leads to the relative inertia of the governing bodies to be pro-active in the anti-drugs campaign.

The inception of the World Anti-Doping Agency (WADA) after the 1998 Winter France drugs fiasco provided a way forward to standardise and implement anti-doping policy across the world by an independent body.

Problems and solutions to anti-doping policy are addressed. The major problem is inadequate definition of doping—to quote Arthur Gold “The definition lies not in words but in integrity of character.”. It is interesting to note that those behind the athlete, namely coaches, administrators, medical profession, and scientists, all seem to lose perspective along with their ethics and “integrity of character” when the race for “gold” is on. Dying to win suggests that these people should be held just as accountable as the athletes themselves. Another unfortunate aspect of anti-doping policy is the difficulty in detecting some abused drugs and the fact that these strategies often lag behind the ability of the pharmaceutical industry to develop new drugs, often for genuine medical reasons but with the unfortunate ability to enhance performance. Education is proposed as a key aspect to anti-doping policy, and parallels with its success in the use of recreational drugs are made. Governments also play a role in limiting supply, decreasing demand for drugs, and the implementation of independent bodies to carry out testing. The success of anti-doping policy is also hard to measure. Fewer positive tests may simply reflect a move to less detectable methods rather than a decrease in use, and success may be better measured in terms of fewer world records.

Dying to win gives an accurate account of the problem of doping in sport and the difficulties and complexities in finding solutions to the problems. It makes interesting and provocative reading for anyone with an interest in sport, from the athlete and coach to the sport administrator, the medical profession, and governments.
1st World Congress on Sports Injury Prevention
23–25 June 2005, Oslo, Norway

This congress will provide the world’s leading sports medicine experts with an opportunity to present their work to an international audience made up of physicians, therapists, scientists, and coaches. The congress will present scientific information on sports injury epidemiology, risk factors, injury mechanisms and injury prevention methods with a multidisciplinary perspective. Panel discussions will conclude symposia in key areas providing recommendations to address the prevention issue in relation to particular injuries and sports.

Further details: Oslo Sports Trauma Research Centre and Department of Sports Medicine, University of Sport and Physical Education, Sognsven 220, 0806 Oslo, Norway. Email: 2005@congress@nih.no; website: www.ostrc.no

Osteosynthese International 2005
15–17 September 2005, Curiohaus, Hamburg
Congress-Chairman: Johannes M. Rueger, M.D., Professor and Chair Topics:
- Innovations in intramedullary osteosynthesis
- New frontiers in osteoporosis and fracture treatment
- Current trauma research
- Special topic: Recent development in pelvic and acetabular fractures

Abstract submission deadline: 31 March 2005
Further details: INTERCONGRESS GmbH, Martin Berndt, Düsseldorfer Str. 101, 40545 Düsseldorf-Germany. Tel: +49 211 585897-80; fax: +49 211 585897-99; email: martin.berndt@intercongress.de; website: www.osteoint2005.de

4th European Sports Medicine Congress
13–15 October 2005, Lemesos, Cyprus

CALANDER OF EVENTS

UK Radiological Congress (UKRC) 2005
6–8 June 2005, Manchester, UK

The UK Radiological Congress (UKRC) meeting will encompass the medical, scientific, educational, and management issues that are of interest and relevance to all those involved in the diverse fields of radiological sciences and oncology. The UKRC provides a forum in which to bring together clinicians, scientists, radiographers, technicians, and other professionals to present and discuss the latest developments and challenges in diagnostic imaging, radiotherapy, and allied radiological sciences.

Key subjects to be covered include: diagnostic radiology; ultrasound; nuclear medicine; interventional radiology; veterinary radiology; emerging technologies; image analysis; computer applications; PACS; radiobiology; radiological physics; management & audit; computed tomography; magnetic resonance; equipment development.

Expected attendance (conference and exhibition): 4000
Further details: UKRC 2005 Organisers, PO Box 2893, London W1A 5RS, UK; Website: www.ukrc.org.uk; Fax: +44 (0)20 7307 1414; Conference tel: +44 (0)20 7307 1410, Email: conference@ukrc.org.uk; Exhibition tel: +44 (0)20 7307 1420, Email: exhibition@ukrc.org.uk

CORRECTIONS

do: 10.1136/bjsm.2004.000044corr1

Cicharro J L, Hoyos J, Gómez-Gallego F, et al. Mutations in the hereditary haemochromatosis gene HFE in professional endurance athletes (Br J Sports Med 2004;38:388–94). The multiple regression equation within the Abstract section of this paper was published incorrectly. The correct equation is:

\[
\text{HSR} = 37.79 - (0.335HFI + 10.09SSP + 2.24STE) \\
\pm 2.34
\]

We apologise for this error.

Sran M M. To treat or not to treat: new evidence for the effectiveness of manual therapy (Br J Sports Med 2004;38:521–5). The volume number for reference 23 (Sran et al) was incorrectly published as 24; the correct volume number is 29.

In Table 2 the results for Giles and Muller should read: Greater short term benefit for back pain with manipulation, but not for neck pain. Acupuncture more effective for neck pain.

In the section “Definitions and search strategy” in the first line of paragraph 2 should read: I searched Medline, Cinahl, and Embase databases for randomised clinical trials comparing manual therapy, including spinal joint mobilisation (with or without manipulation) or manipulation only with other conservative treatments for back or neck pain.

We apologise for these errors.
