Release of α-actin into serum after skeletal muscle damage

A Martínez-Amat, H Boulaz, J Prados, J A Marchal, P Padial Puche, O Caba, F Rodríguez-Serrano, A Aránega

Objective: The skeletal muscle protein α-actin was investigated in the serum of subjects with severe skeletal muscle damage to assess its utility as a reliable and predictive marker of muscle damage.

Methods: Serum samples were obtained from 33 healthy controls and 33 patients with severe skeletal muscle damage, defined by a total creatine kinase value of >500 IU/l (Rosalki method). Troponin I, troponin T, and myoglobin concentrations were determined by immunoassay and α-actin concentrations by Western blot and densitometry.

Results: The mean serum concentration of α-actin in controls and patients with skeletal muscle damage was 600.9 and 1968.51 ng/ml, respectively, a statistically significant difference. Sera of patients with muscle damage showed higher levels of α-actin than of troponin or myoglobin. No significant difference in troponin I levels was observed between the groups.

Conclusions: According to these results, α-actin was the most significant skeletal muscle damage marker analysed and may be an ideal candidate for the identification of all types of myofibre injury, including sports injuries. Our findings support the use of α-actin as a marker alongside other currently used biological proteins.

Muscle injury, defined as injury of skeletal muscle involving the rupture of muscle fibres, is one of the most common reasons for consulting a sports medicine specialist. A training burden that is poorly tolerated by the organism is often the cause of these injuries, and is the result of an inappropriate training program or the inadequate physical condition of the individual. The symptoms of muscle damage are polymorphous, non-specific, deceptive, and slow to develop. However, early diagnosis is important, because the sooner treatment is started, the greater the possibility of reversing the symptoms and reducing the severity of muscle damage.

The biological diagnosis of muscle damage is largely based on immunoassay determination of the serum activity of sarcoplasmic enzymes such as creatine kinase (CK) or lactate dehydrogenase. An increase in the serum activity of these intracellular enzymes reflects their escape through the membrane of injured cells. However, this method has some drawbacks. First, the findings do not clearly indicate structural muscle damage, as demonstrated by histological studies, and the speed and reliability of the diagnosis are inadequate. Second, serum CK levels may not be increased with muscle damage or may only reflect muscle overload.

Finally, the specificity of CK measurement by this method can be reduced by interference from other kinases (for example, adenylyl kinase, whose catalytic concentration in plasma is increased by haemolysis), CK isozymes (CKMB or mitochondrial CK), and CK-immunoglobulin complexes known as macrokinases. Thus, CKMB is co-expressed in both skeletal muscle and the myocardium, and its serum or plasma activity can be increased by muscle alterations when no myocardial necrosis signs are observed by even the most effective imaging methods.

The detection of even small amounts of proteins bound to intracellular structures (mitochondria, nucleus, cellular contractile apparatus) always indicates necrosis. Thus, troponins and α-actin have been used as biochemical markers of heart damage. Subunits T, C, and I of troponin are proteins of the contractile apparatus found in different isoforms according to the muscle type. Thus, cardiac specific isoforms (cTnI) have been used to determine exercise induced heart muscle damage and myocardial damage during cardioversion of atrial fibrillation, although their delayed release into the bloodstream severely limits their diagnostic efficiency. α-Actin has been used as a molecular marker of ischaemic heart disease, and studies have confirmed its presence in the sera of patients with unstable angina as well as its high sensitivity (63–100%) and earlier release compared with cardiac specific troponins. The effectiveness of α-actin as a marker of muscle damage and its abundance in muscle, where it represents 20% of all cell proteins, make it a promising candidate as a new marker of skeletal muscle damage.

The objective of this preliminary study was to use the Western blot technique to measure the release of skeletal α-actin into the serum of patients with severe skeletal muscle damage, discriminating for possible interference by cardiac actin by means of a troponin study of myocardial damage. The sensitivity of Western blot and the biological material used (serum obtained by a simple extraction of blood without need for biopsy) offer two major advantages for the study of skeletal muscle damage. Our results suggest that skeletal α-actin may be a specific marker of muscle damage that could be measured when treating elite sportsmen and women. If α-actin proves to have diagnostic value, it might allow the development of a fast and easily applied test to assess in situ the severity of skeletal muscular injury in sports people.

METHODS
Subjects
Blood samples were obtained from 33 consecutive patients immediately after their arrival at the Emergency Department of the Trauma Centre of the Virgen de las Nieves University Hospital of Granada with skeletal muscle damage caused by severe trauma (accidents, bruises, etc). The patients were aged from 22 to 80 years; 24 were male (72.7%) and nine female (27.3%), with a mean age of 43.8 and 55 years, respectively. Ethical committee approval had been obtained for the study. Blood samples (5 ml) were extracted with patients’ informed written consent. The selection criterion...

All data are expressed as mean ± SEM of four measurements. The significance of the differences (*) between the control and muscle damage groups was determined by the Wilcoxon test. A significant difference was considered when p < 0.001. The median value is indicated in parentheses.

was the presence of a total CK value of >500 IU/l by the Rosalki method (Beckman Instruments, Madrid, Spain).

Control assays were performed in 33 serum samples collected at the Granada Regional Blood Bank from 24 healthy males (72.7%) and nine healthy females (27.3%) with a mean age of 54.5 and 76.3 years, respectively. These donors ranged in age from 22 to 79 years.

Serum samples were obtained by venopuncture and collected in tubes with separator gel (Venoject II, Terumo Europe, Leuven, Belgium). After clotting, they were centrifuged for 10 min at 5000 rpm (Beckman Instruments Centrifuge). The sera were then aliquoted into 1.5 ml Eppendorf tubes for the determinations.

Determination of total CK activity

The enzymatic kinetic method was used to determine total CK activity. In the reaction, the CK catalyses the transfer of a phosphate group from creatine phosphate to adenosine diphosphate. The subsequent formation of adenosine triphosphate group from creatine phosphate to adenosine diphosphate is measured by using two associated reactions, catalysed by hexokinase and glucose-6-phosphate dehydrogenase, which produce nicotinamide adenine dinucleotide. The production of photons is inversely proportional to the amount of enzymatic conjugate present at the end of the reaction and, consequently, to the concentration of cardiac troponin I and myoglobin in the sample. The amount of analyte in the sample was determined using a multipoint calibration curve.

For the troponin T determination, the Elecsys 2010 troponin T test (Roche Diagnostic, Indianapolis, IN) was used, which is performed in 18 min at 37˚C. In a first incubation step, a sandwich-type complex was formed by the sample, a specific biotinylated monoclonal antibody against troponin T, and a ruthenium chelate labelled (chelate tris(2,2’-bipyridyl)ruthenium(II), (Ru(bpy)2+3) specific monoclonal antibody against troponin T.

Detection of α-actin by Western blot

Sarcomeric α-actin was determined by Western blot. A sample of serum (5 μl) from each study subject was dissolved in Laemmli’s sample buffer (62.76 mm Tris-HCl pH 6.8, 1% 2-mercaptoethanol, 1% SDS, 10% glycerol, and 0.01% bromophenol blue) at 1:5 ratio, boiled for 5 min, microfuged for 1 min, and analysed by SDS-PAGE (sodium dodecylsulphate polyacrylamide gel electrophoresis) in a Mini Protein II cell (Bio-Rad, Hercules, CA) at 60 mA for 1 h at room temperature. The gels with samples of serum were run in duplicate in all cases. The gels for immunoblot analyses were separated electrophoretically and transferred to a nitrocellulose membrane by applying a current of 20 V at room temperature for 30 min. The blots were treated with blocking solution (20 mM Tris, 0.9 NaCl, 10% non-fat milk) for 3 h at room temperature and then reacted with a 1:2000 dilution of anti-sarcomeric α-actin monoclonal antibody (Alpha-Sr-1 Clones, Dako, Glostrup, Denmark). Primary antibodies were incubated overnight at 4˚C. Membranes were washed (15 min in 5% TBST) and incubated with horseradish peroxidase conjugated rabbit anti-mouse IgG (1:2000, Sigma-Aldrich, St Louis, MO) for 1 h at room temperature, followed by additional washes (15 min in 5% TBST). Proteins were visualised by enhanced chemiluminescence (ECL, Bonus, Amersham, Little Chalfont, UK).

Densitometric analysis of α-actin

Densitometric analysis was carried out by scanning x ray images of the membranes (Fluorine-S Multitagger, Bio-Rad). The resolution of the images was 100 pixels per inch. A densitometry image analysis software package (Quantity 1, Bio-Rad) was used. The procedure was repeated for every sample processed in this study. A digital image was obtained formed by 66 wells, 33 with control group and 33 with skeletal muscle damage group samples.

A standard curve was obtained by immunoblotting with an amount of known proteins (nanograms of pure α-actin) and densometrically quantifying the bands obtained.
Levels of α-myoglobin in sera of patients with skeletal muscle damage. Number 1 corresponds to the positive control (80 ng/ml of pure α-myoglobin) and numbers 2–10 to the levels of α-myoglobin in sera of healthy subjects. (B) Levels of α-actin in sera of patients with skeletal muscle damage. Number 1 corresponds to the positive control (80 ng/ml of pure α-actin), and numbers 2–10 to the levels of α-actin in sera of subjects with skeletal muscle damage.

DISCUSSION

Major questions have been raised in sports medicine about the diagnosis of skeletal muscular damage. Are there any faithful, reliable, sensitive, and reproducible markers of muscular injury? Do variations in these biological markers correlate with the severity of histological injury? Are increases in these markers associated with overtraining? There appears only to be a consensus that intense physical exercise induces injury of the muscle fibres, and that the severity of these injuries depends on the duration of the exercise, its characteristics, and the training level of the individual.35

Clinical assessment of exercise-induced muscle injuries is very difficult. The severity and evolution of these structural injuries are highly variable, and they are characterised by simple residual pains in muscle masses and sometimes by a persistent sensation of heaviness in the lower limbs. Because the clinical expression of this pathology is non-specific, its impact in sports remains difficult to estimate.35

The ideal marker should be muscle specific with a high intracellular concentration, and it should be rapidly released in the event of injury and be stable, maintaining its elevated concentration in blood for an adequate time period. It should have a high diagnostic sensitivity, especially in the first few hours after the injury, and have a diagnostic specificity as close to 100% as possible.14

Variation in CK activity is currently used as an indicator of muscle damage.1,26,27 The present study demonstrated differences in total CK activity between healthy individuals and those with muscle damage. However, Kuipers and Keizer concluded that it can never be considered a reliable marker of muscle damage, because the presence of total CK in plasma does not faithfully reflect the extent and nature of muscle injury36 due to interferences produced by isozymes (CKMM, CKMB, and CKBB) of different origin. Bigard37 reported that the extent of exercise-induced muscle damage cannot be assessed solely on the basis of variations in CK activity. The lack of sensitivity and reproducibility of CK activity has led to

**RESULTS**

Sera of the muscle damage group showed a mean CK activity in serum of 2041.9 IU/l (range: 517–8943 IU/l), significantly (p<0.001) higher than the level of 105.5 IU/l (range: 15–545 IU/l) found in the control group sera (table 1).

The muscle damage group showed a mean troponin I (cTnI) value of 0.035 ng/ml (range: 0.001–0.085 ng/ml) compared with 0.0072 ng/ml (range: 0.001–0.220 ng/ml) and that in the control group, a non-significant difference (fig 1). There was a significance (p<0.001) difference between the mean value of troponin T (cTnT) in the muscle damage group vs. the control group was 1968.51 ng/ml (range: 854–2594 ng/ml), significantly (p<0.001) higher than the concentration of 600.90 ng/ml (range: 0.00–1339 ng/ml) in the control group (table 1, fig 3).

Circulating α-actin was detected by immunoblotting as a band located at 43 kDa (fig 2). The serum protein concentration was determined by densitometric study of the α-actin bands. The mean serum α-actin level in the muscle damage group was 1968.51 ng/ml (range: 854–2594 ng/ml), significantly (p<0.001) higher than the concentration of 600.90 ng/ml (range: 0.00–1339 ng/ml) in the control group (table 1, fig 3).

**Statistical analysis**

Because only α-actin followed a normal distribution among the variables studied, a non-parametric Wilcoxon test was applied to all variables. Student’s t test was used to compare α-actin concentrations between the groups. Data were entered into a personal computer and statistical procedures were performed using the SPSS statistical package (v. 11.5; SPSS, Chicago, IL). Statistical significance was preset at the p<0.001 level.

**Figure 2** Representation of mean α-actin and myoglobin levels in control group and muscle damage group sera. *Indicates significant differences between the groups.

**Figure 3** (A) Immunoblotting determination of α-actin levels in control group sera (healthy subjects), with a band at the level of 43 kDa. Number 1 corresponds to the positive control (80 ng/μl of pure α-actin) and numbers 2–10 to the levels of α-actin in sera of healthy subjects. (B) Levels of α-actin in sera of patients with skeletal muscle damage. Number 1 corresponds to the positive control (80 ng/μl of pure α-actin), and numbers 2–10 to the levels of α-actin in sera of subjects with skeletal muscle damage.
Biological diagnosis of muscle damage is based on immunoassay determination of the serum activity of sarcoplasmic enzymes. The detection of even small amounts of proteins bound to intracellular structures always indicates necrosis. Thus, troponins and α-actin have been used as biochemical markers to detect heart damage. Troponin isoforms (cTnI and cTnT) are confirmed as heart damage markers but are not useful as skeletal muscle damage markers.

What is already known on this topic

α-Actin is an abundant protein in the muscle, where it represents >20% of all cell proteins. In this study, we demonstrate α-actin efficiency as a marker of muscle damage suggesting its potential use as a new marker of skeletal muscle damage. As our results show, α-actin was the most significant skeletal muscle damage marker analysed. We therefore propose it as candidate for the identification of all types of myofibre injury.

What this study adds

Detection of α-actin after muscle damage
