The Harstad injury prevention study: the epidemiology of sports injuries. An 8 year study

Børge Ytterstad

Abstract

Objective—To describe the epidemiology of sports injuries occurring in a community during 8 years and to evaluate the outcome of an intervention implemented against injuries occurring in downhill skiing.

Methods—Hospital treated sports injuries occurring in Harstad, Norway (population 22 600) were recorded prospectively during an 8 year period. A prevention programme targeting downhill skiing injuries was evaluated.

Results—2234 sports injuries accounted for 17.2% of recorded unintentional injuries. Two out of three injuries occurred in team sports. Soccer accounted for 44.8% of all sports injuries. Downhill skiing injuries had higher mean score on the abbreviated injury scale than all other sports analysed combined ($P < 0.01$). Postintervention injury rates for downhill skiing were reduced by 15% when adjusting for exposure ($P = 0.24$). Further observations are needed for assessing the effectiveness of the downhill skiing safety programme.

Conclusions—Strategies for future sports injury prevention include community involvement, particularly sports organisations. Local data analysis seems to justify some priorities, for example, promotion of helmet use in downhill skiing for young adolescents and prevention of lower limb fractures in male soccer players 15+ years old. Prospective hospital recording of injuries provides a tool for the design and outcome evaluation of sports injury intervention research.

(Br J Sports Med 1996;30:64-68)

Key terms: soccer; downhill skiing; sports; injury; prevention

Sports injuries are an important cause of morbidity in Norway, with incidence ranking next to injuries in the home.¹ Because of the high incidence, sports injuries needing hospital treatment require considerable outpatient and inpatient resources.²⁻³ The World Health Organisation has emphasised the importance of injury control (*Health for All Year 2000*). The goal for Europe is to reduce injury, disability, and death from accidents, including sports accidents, by at least 25%.⁴ High quality epidemiological data are essential for the planning, development, and evaluation of efforts to prevent injuries.⁵ For local sports injury prophylaxis the use of national aggregate data is of limited value because different populations

seem to have special epidemiological characteristics²⁻⁶⁻⁷ and the use of local data is advantageous for selecting targets for injury prophylaxis.⁸

Different approaches for preventing sports injuries have been recommended: for example, promotion of protective equipment use,⁹ adequate warming up before competition,¹⁰ or the implementation of a routine prophylaxis programme before training or games.¹¹ The latter was found to be effective for prevention of soccer injuries.¹¹ In a community based injury prevention study in Sweden a significant decrease in overall injury rates was reported, but the study did not specifically target sports injuries.⁸ Although a few studies have described prospective and complete recording of sports injuries in a defined population,²⁻³ ours is the first prospective study of such long duration (eight years), including a preventive part.

The aims of this study were to describe the epidemiology of sports injuries occurring in a community during eight years and to evaluate the outcome of an intervention implemented against injuries occurring in downhill skiing.

Methods

STUDY DESIGN

The present paper describes the sports injury component of the comprehensive Harstad injury prevention study.¹²⁻¹⁴ The city of Harstad has a population of 22 600 and is located 250 km north of the Arctic circle. The study lasted for eight years. The intervention component (downhill skiing) had a baseline of five years and an intervention period of three years.

DEFINITION

A sports injury was defined in this study as an unintentional injury occurring during games or physical training in an area specially designed for sports activities, for example soccer stadiums, gymnasiums, downhill skiing slopes, ski jumping installations, and skating rinks. Injuries occurring during horseback riding or during non-competitive physical exercise in the open air and recreational areas are excluded.

DATA RECORDING

The prospective data recording started 1 July 1985 and lasted for eight years. During this time data on all injured persons treated in the hospital emergency ward were recorded, and included in an injury database. The variables for each case were selected in cooperation with The National Institute of Public Health¹ as part of a national injury surveillance system and followed the Nordic coding system.¹⁵

VARIABLES IN THE INJURY DATABASE

Demographic data collected were age, gender, and place of residence. Activity type, place of injury, type of sport, product involved, and date and time of injury were recorded. An open ended question (free text) described the event leading to the injury. This free text contained three distinct parts that are partly consistent with the concepts of precrash, crash, and post-crash described by Haddon.¹⁶ Medical variables were injury type, injury mechanism, body part injured, and admittance to the hospital. Injury severity was coded according to the abbreviated injury scale (AIS).¹⁷

DATA RECORDING PROCEDURE, ANALYSIS, VALIDITY, AND RELIABILITY

The recorded variables, data recording procedure, and measures taken to ensure data validity and reliability of the injury database are described in more detail elsewhere.¹²⁻¹⁴

To aid prophylaxis planning, a separate analysis was completed for children (0-14 years) and adolescents/adults (15+ years).

DOWNHILL SKIING INJURY PREVENTION

Harstad municipality has one ski resort (opened in 1985) with ski lift and slopes for downhill skiing, run by the Harstad Alpine Club. Practically all hospital treated downhill skiing injuries come from this installation. Data from injured skiers recorded during the first years of the present study were analysed and discussed in the Harstad community injury prevention group (IPG). The function and composition of this group is described elsewhere.¹²⁻¹⁴ The data with free texts (victim stories) were sent to the Harstad Alpine Club, together with some recommendations for targeting interventions: (1) promotion of increased helmet use and properly fitted boots and bindings; (2) prevention of injuries occurring from collisions with trees and rocks while skiing outside the downhill area; (3) prevention of injuries resulting from high speed skiers within the area running into objects or other skiers; and (4) prevention of injuries connected with the ski lift.

STATISTICS

Because of warmer winters in the intervention period, injury rates for downhill skiing were adjusted for exposure. For the other sports, the incidence rates given were not analysed with regard to duration of exposure to the sporting

activity, but were based on population census data. Epi info version 5.01 package was used for analysis.¹⁸ The χ^2 test was used for testing injury rate changes and incidence rate differences.¹⁹ The Kruska-Wallis test was used for comparing means. P values below 0.05 were regarded as significant.

Results

INJURY RATE VARIATIONS DURING THE STUDY

Of 12 977 unintentional injuries recorded in Harstad residents from 1 July 1985 to 30 June 1993, 2234 (17.2%) were sports injuries, yielding a mean sports injury rate of 12.5 per 1000 person-years. During the study the yearly overall crude sport injury rate was stable (table 1).

AGE AND SEX DISTRIBUTION FOR INJURY MECHANISM, INJURY TYPE, AND BODY PART INJURED

Of the injured, 63.4% were males who, compared with females, had a higher mean injury rate (16.0 v 9.1 per 1000 person-years, $P < 0.01$) and were older (21.8 v 17.2 years, $P < 0.01$); 80.5% of injuries occurred in people between 10 and 30 years of age (figure).

Injury mechanism

Falls and trauma from contact with persons or objects accounted for three out of four injuries. The sex distribution of injury mechanisms for two different age groups is shown in table 2.

Injury type

Of those injured, 49.6% had sprains (partial or total ligament ruptures) or dislocations, 23.3% had open wounds, excoriations, or contusions, 18.4% had fractures, and 2.6% had concussions or more serious brain injury. Internal injury (other than intracranial) was observed in 0.8%, and 5.5% had multiple injuries, other injury types, or no information. The injury type variations by sex and different age groups are shown in table 3.

Body part injured

As a mean of overall recorded injuries, lower extremities were injured in 54.1%, upper extremities in 29.5%, the head in 10.0%, and other or multiple body parts in 5.9% of cases. In children, boys suffered injuries of the head, thorax, abdomen, and spine more often than girls (data not shown). Data about body part injured were missing in 0.4% of cases.

The Harstad injury prevention study: age and sex specific sports injury rates (n = 2234) recorded during eight years, starting 1 July 1985.

INJURY DISTRIBUTION AND CHARACTERISTICS WITHIN SPORTS

Sex variation

Soccer accounted for most injuries, followed by downhill skiing. Males injured while playing soccer represented 36.8% of the population injured, and 9.1% were female handball players (table 4).

Injury type and seriousness according to abbreviated injury scale

One hundred and eighty nine fractures and 499 sprains in soccer accounted for 30.1% of all

injuries. Fractures and concussions were the most frequent types of injury in downhill skiing. All but one injury (a downhill skiing injury with AIS 5) had AIS < 4. The mean AIS score was higher in downhill skiing than in all other sports analysed combined ($P < 0.01$). Little variability was observed between the other sports (table 5).

ADMITTED CASES

The variable “admitted to hospital” was recorded for the seven last years of the study, during which 5.6% of the recorded sport injuries led to admittance ($n = 112$). Soccer accounted for 30.4% and downhill skiing for 28.6% of admittances, while 41% of admitted cases occurred in all other sports combined. Females were admitted in 3.3% of recorded cases and males in 7.0%. Mean age was 24.5 years for males and 21.9 for females. Of the admitted cases, 29.5% had fractures, 26.8% had ligament ruptures, wounds, contusions, or dislocations, 25.0% had concussions or more serious neurological deficit, 1.8% had internal injury other than intracranial, 3.6% had multiple injuries, and 13.4% had other injury types.

Table 4 Distribution of injuries by sport and sex

Sport	n	Males* %	P†	% of total
Soccer	1001	82.3	0.00	44.8

Table 6 Injury count and rates per 10 000 person-years (in parentheses) for different sports by study period. Period 1 (5 years) = baseline; period 2 (3 years) included interventions for downhill skiing

	Soccer	Handball	Volleyball	Basketball	Downhill	Other	Missing
Period 1	617 (55.6)	146 (13.2)	100 (9.0)	64 (5.8)	179 (16.1)	263 (23.7)	32 (2.9)
Period 2	384 (56.8)	100 (14.8)	55 (8.1)	31 (4.6)	72 (10.6)	172 (25.4)	19 (2.8)
Relative risk for period 2	1.02	1.12	0.90	0.80	0.85*	1.07	0.97
P value	0.767	0.402	0.599	0.345	0.24*	0.500	0.955

*Adjusted for exposure.

INTERVENTION: INJURY RATES FOR DOWNHILL SKIING COMPARED TO OTHER SPORTS

A 15% decrease in downhill skiing injury rates was observed between the five year baseline period and the three year intervention period (adjusted for exposure, $P = 0.24$). Concomitantly the injury rates were more or less stable in the other sports (table 6). The admittance rate for downhill skiing injuries was reduced from 2.8 per 10 000 person years (the last four years of baseline) to 1.0 per 10 000 person years (intervention period) (data not shown).

Discussion

THE LOCAL EPIDEMIOLOGY OF SPORTS INJURY

Some of the epidemiological characteristics in our study are similar to other Scandinavian studies describing prospective injury recording: for example, the proportion of sports injuries relative to all injuries, mean age, female to male ratio, and the dominant position of soccer in the injury panorama.³⁻⁶ There are, however, some differences in the proportion of different sports injuries, mostly accounted for by geography and local cultural differences. Downhill skiing injuries had the highest frequency of fractures and concussions. This is consistent with a significantly higher AIS score in this sport. Nevertheless, while injuries sustained in downhill skiing were a major problem in our study, they are much less so in the studies from the flat parts of Sweden.³⁻⁶ Ice hockey, however, which accounted for a major part of sport injuries in these Swedish studies, is uncommon in Harstad.

TRENDS FOR SPORT INJURY RATES

The stability of overall sports injury rates observed during an eight year period may be interpreted as an indication of a reliable and stable hospital injury recording system. This assessment could be biased by (1) an increasing risk exposure due to a population increasingly participating in sports activities, and (2) a registration loss at the end of the study (registration effect). However, to our knowledge, participation in sports related activities has not been on the rise in Harstad. The possibility of a registration effect has been assessed earlier,¹²⁻¹⁴ and was found to be an unlikely occurrence. Information for assessing exposure was only available for downhill skiing. Data from the Harstad Alpine Club (personal communication) indicated a lower exposure during the last three years of the study (intervention period) compared to the first five years (baseline). Due to weather conditions, the ski resort had fewer days open per year during the last three years (intervention period) compared to baseline. The relative risk of

getting a downhill skiing injury between the baseline non-intervention period and the intervention period, when adjusted for the above mentioned exposure difference, was 0.85 (confidence intervals 0.66, 1.10) ($P = 0.24$). These figures must be interpreted with caution. Future injury rate calculations based on continuous prospective recordings may help to indicate whether the ongoing downhill safety programme is effective or the calculated 15% injury rate reduction is due to random variations in accidents.

PREVENTION STRATEGIES

General strategic planning should take into consideration the major epidemiological findings in this study, for example, age and sex distribution, main injury mechanisms, injury type, and body part injured.

School involvement

Given that sports injuries occur most often during the second decade of life (figure), it seems reasonable to involve schools more in prophylaxis, for example, information to individuals, parents, and coaches. The latter are often recruited from parents or teachers.

Protective equipment

Nearly half of the injured children were injured in falls. This could indicate a need for more sturdy footwear for children engaged in sports. Male children suffered head injuries and concussion most frequently (table 3). Out of 31 head injuries observed in downhill skiing, 17 (55%) occurred in 11–15 year olds (data not shown). This could indicate resistance in Harstad to helmet use in this age group. Such resistance has been reported by others.⁹ A Swedish study of injuries in downhill skiing reported a distinct decline in helmet use from 66% in 9–11 years old children to 21% in 12–14 year olds.⁹ Strategies for achieving increased helmet use in this age group must be given priority. Mandatory helmet use should be considered.

Team sports

Team sports accounted for two out of three injuries, soccer injuries being the most frequent (table 4). Obviously the prevention of team sport injuries in general and soccer injuries in particular must be given high priority. Ekstrand *et al* have shown that a prevention programme can reduce soccer injuries by as much as 75% (including overuse injuries).¹¹ The programme is made up of seven different parts and can be used in most team sports: correction of training, protection by correct equipment, prophylactic ankle taping, controlled rehabilitation after injury, exclusion of

players with knee instability, information to coaches and players, correction and supervision by doctors and physiotherapists.

Out of 1001 soccer injuries in our study, 63.8% occurred in the lower extremities (data not shown). Fractures are costly to patients and the health services in terms of suffering, debility, and expenditure of hospital resources. Accordingly this injury type should be a high priority target in planning prophylaxis. Fractures of the lower extremities occurring during tackles in soccer can be prevented by the use of proper protective equipment (shin guards).¹¹ Our data showed that males 15+ years old suffered 53 out of 71 fractures of lower extremities occurring in soccer, identifying them as an important subgroup for intervention. Strategic considerations for prophylaxis should include checks on compliance with mandated use of shin guards and adequate referee reaction to rule violations.

According to the principle adapted by the Harstad injury prevention programme, effective prophylaxis may be initiated by the injury prevention group (IPG) and planned/implemented in cooperation with relevant organisations,^{12-14 20} for example, the local branches of the Norwegian associations for the team sports (soccer, handball, volleyball, basketball), municipal authorities, and the health services.

Individual sports

The most important individual sport in our study is downhill skiing. A renewed effort for further cooperation with the Harstad Alpine Club is needed in promoting the observation of safety regulations, use of correct bindings and protective equipment, and supervised and directed skill training. This model for prophylactic work can be used in most individual sports.

CONCLUSIONS

(1) Continuous prospective hospital recording of sports injuries in a community is feasible and provides a tool for evaluating the outcome of sports injury prevention programmes. (2) Local sports injury prophylaxis may be improved by using local epidemiological knowledge in community based interventions. (3) Although a postintervention 15% reduction was observed

in downhill skiing injury rates (adjusted for exposure), the present study has not presented conclusive evidence of an effective intervention against downhill skiing injuries in Harstad. A basis is provided for designing an injury prevention programme covering most sports.
