Sledging related spinal injuries and fracture patterns: a report on five cases

S Basu, N K Makwana, R Khazim

Abstract

The cases are reported of five patients who presented to The Queens Medical Centre, Nottingham after a sledging accident. All five patients presented consecutively during the first weekend in 1997 having sustained the accident in the same public park. The mechanism and subsequent fracture type is described for each. These injuries are preventable, and increasing public awareness of the risk of sledging in public places may reduce the incidence. (Br J Sports Med 1999;33:357–359)

Keywords: sledging; spine; fracture; injury

Sledging is a popular sport during the winter. Unfortunately, it is associated with a high incidence of musculoskeletal injuries. Sloan et al. reported on 101 patients with various sledging related injuries seen in one accident and emergency department over an eight day period. Spinal injuries are rare but they account for a significant number of patients with long term morbidity. The factors leading to such injuries, the mechanism, and the outcome have not been previously reported. We report on five patients who sustained a spinal injury while sledging, and discuss these factors.

Case reports

Five patients, aged 15–38 years, with a spinal injury following a sledging accident were admitted to the Queen’s Medical Centre during the first weekend of January 1997. Of 2617 accident and emergency attenders during that week, five (0.2%) had sustained a spinal injury. All five were sledging in the same public park. The runs used were not designated for this activity. Not surprisingly, therefore, it is associated with significant injuries. These have ranged from acute myocardial infarction to a variety of extremity musculoskeletal injuries. Spinal injuries are rare and the factors leading to such injuries, the mechanism, and the outcome have not been previously reported. We report on five patients who sustained a spinal injury while sledging, and discuss these factors.

The first patient hit an obstruction and was thrown up in the air after hitting an obstruction. None of the injuries were alcohol related.

All five patients sustained thoracolumbar fractures (T12–L2; fig 1) without neurological injury. The mechanism in all five was predominantly axial compression with flexion. Further imaging with computed tomography scanning was obtained in three patients to delineate the fracture pattern further. Two of these underwent surgical intervention to reduce the spinal canal compromise in one and to stabilise the spine in another.

All patients were treated by thoracolumbar orthosis and early mobilisation. All fractures united without complications, and, in the two patients who had surgery, the spinal instruments were removed electively nine months after the injury.

Discussion

Sledging is a popular recreational sport during the snow season. Prolonged snowfall in this country occurs only occasionally and usually during the month of January. It usually triggers a rush to the nearest slope with a sledge and very little planning. Not surprisingly therefore it is associated with significant injuries. These have ranged from acute myocardial infarction to a variety of extremity musculoskeletal injuries. Spinal injuries are rare and the factors leading to such injuries, the mechanism, and the outcome have not been previously reported. Silver reviewed all sledging related injuries seen in a spinal unit over a 50 year period from 1944, and found six spinal cases, five of which were sustained abroad. Sloan et al. reported on 101 consecutively seen patients with a sledging injury and found five who had a spinal injury. In our study, five patients presented consecutively over one weekend having sustained these injuries in a single public park. These five patients represent a small percentage (0.2%) of the injuries treated at the Queens Medical Centre during that week. However, five cases in seven days was a high case load for the spinal unit. In our group of patients, an obstruction on the slope was responsible for the injury in four out of the five cases. Bjornstig and Tordai reviewed 271 patients and found an obstruction on the slope was the main cause of injury. In our study, other factors may have also contributed to these injuries, including selection of improper sledging material and sledging on steep slopes or slopes with many ridges. Sledging in areas not designated for this activity increases the risk.
chances of meeting an obstruction. It was interesting to note that, although snow was on the ground soon after Christmas in 1996, the injuries occurred three or four days later. Time and use could have made the slopes firmer and more slippery than at first, resulting in the generation of greater speeds. The high speeds achieved may have been a significant factor in the number of spinal injuries observed. Spinal injuries caused by sledging are uncommon and the mechanism of injury is poorly defined. Our study suggests that the main mechanical force is an axial compression/flexion one, predominantly involving the thoracolumbar region. They may be complicated by spinal canal compromise or instability requiring spinal surgery with instrumentation. In our study, the average hospital stay was six days. Sledging injuries have significant economic implications, and increasing public awareness and the designation of suitable slopes without obstructions may reduce the incidence.

Confounders: S B initiated the study and participated in data collection, analysis, and writing of the paper. N K M initiated the study and research and participated in data collection, analysis and writing of the paper. R K initiated the study, developed the core issues, and participated in analysis of the data and editing of the paper.

Take home message
Sledging can result in significant spinal injury. Increasing public awareness, sledging on designated slopes without obstructions, and the use of suitable equipment may prevent serious injury.
Commentary

It is interesting that the study included five spinal injuries from one weekend when the previous papers by Silver and Sloan et al suggested that spinal injuries were rare. The authors suggest that the slope may have been to blame. It is my belief that the climatic changes over the last decade have resulted in lower snowfall which has affected injury rates in two ways. Firstly, as noted in the study, fewer people own appropriate sledges and more use is made of inappropriate sledding materials. Secondly, and perhaps more importantly, the lower snowfall results in inadequately covered slopes where every bump and ridge remains exposed. Inadequately covered slopes are inherently more dangerous but are eagerly sledged on by snow starved budding tobogganists.
