The psychological impact of injury: effects of prior sport and exercise involvement

Lynne H Johnston, Douglas Carroll

Abstract

Objectives—To test the assumption that the psychological impact of injury varies with involvement in sport and exercise, and that those who are more involved in sport and exercise before injury would experience greater negative affect and retarded recovery.

Method—Patients attending for physiotherapy completed a battery of questionnaires including measures of mood and perceived recovery, at the beginning, middle, and end of formal rehabilitation. Complete data were available for 93 patients.

Results—Those who were more involved in sport and exercise before injury registered higher levels of confusion and perceived their recovery to be less, possibly reflecting greater information needs and a greater mismatch between current status and that before injury in the athletic sample. Reported negative affect did not vary with sport and exercise involvement.

Conclusions—Incapacitation for those not involved in sport and exercise before injury may have much the same affective impact as it does for those with considerable involvement. However, those with considerable involvement did report higher levels of confusion and perceived their recovery to be less towards the end of rehabilitation. This suggests that it may be important to assess affective reactions and perceived recovery during the re-entry phase.

Keywords: injury; psychological impact; physiotherapy; rehabilitation; recovery

It is estimated that 29.7 million sports injuries occur annually in England and Wales at a total cost in terms of treatment and lost working days of £991 million.1 Injury to those involved in sport and exercise has also been reported to have a substantial psychological impact. Qualitative studies examining differences between injured and uninjured athletes have disclosed greater negative affect, lower self esteem, and higher levels of depression and anxiety among the injured athletes.2–4 Comparisons of athletes before and after injury have indicated greater mood disturbance, lowered self esteem, and increased depression after injury.5,7 Studies that have charted emotional state over the period of injury have generally found a move from negative to positive affect over time.5,7,11 The degree of this shift appears to be dependent on actual and perceived rehabilitation success.7 Recent qualitative studies also attest to the negative impact of injury in athletes, as well as the shift in affect over time.12–14

A general assumption within much of the sport injury literature, which is increasingly reflected in treatment provision, is that athletes and non-athletes differ radically in the way they respond to injury.15–18 For example, concepts borrowed from analysis of the bereavement process have been applied to account for the emotional impact of athletic injury.9 In addition, those who have championed a cognitive appraisal account of psychological responses to injury argue that the greater the psychological investment in sport and exercise, or the more committed the person is15, then the greater the stress of injury.15 Further, the well recognised psychological benefits of exercise may be jeopardised by injury, with consequences for negative affects such as anxiety and depression.18–19

Nevertheless, the assumption that the psychological impact of injury will vary with psychological and or physiological investment in sport and exercise has received little in the way of formal study. To date, there are only four published reports of sports involvement as a factor in injury impact.11,20–22 Although the results of these studies are indicative, they can hardly be regarded as offering definitive evidence that the psychological response to injury is related to involvement in sport and exercise. With one exception,11 these previous studies have used indirect measures of sport and exercise activity. Further, responses have been assessed to hypothetical rather than real injuries20 and, in other instances, at some considerable time after the injury was sustained.21 In addition, none of these studies included repeat assessments at standard temporal locations during rehabilitation.

This study was undertaken to provide a more rigorous test of the hypothesis that the psychological impact of injury will vary with involvement in sport and exercise, and that those who are more involved will experience greater negative effect consequent to injury. As a consequence, but also as a result of the need to regain their previous high level of physical functioning, it was also expected that those with a greater involvement in sport before injury would also perceive their recovery to be less. Finally, given that the affective impact of injury changes over the course of rehabilitation, it was considered important to perform repeated assessments.

Methods

PARTICIPANTS

Physiotherapists in 40 NHS hospitals, community units, or health centres, 36 private hospitals and physiotherapy clinics, and 23...
Psychological impact of injury

The principal aim of this study was to examine participants’ emotional responses, as well as their perceptions of recovery, in terms of the number of hours of sports participation a week before injury. Given the number of actual and potential analyses with this data set, p<0.01 was adopted in all correlation, analysis of variance, and analysis of covariance statistics to provide greater protection against type I errors.

Results

Complete data at each sampling point for both patient and physiotherapist were available for 93 patients. The mean (SD) age was 35.61 (13.10) years; 55 were men and 38 women. On average, they were involved in sport and exercise for 5.63 (6.05) hours a week before injury. Their mean (SD) injury severity rating was 3.30 (1.11), and the analogous physiotherapists’ rating was 3.39 (0.87); these ratings did not differ significantly.

OUTCOME VARIABLES: CHANGES OVER TIME

With the exception of self rated energy and recovery, which increased over time, all other outcome variables (anxiety, depression, confusion, anger, and fatigue) decreased as rehabilitation progressed. Analysis of variance showed that changes across time were significant. Post hoc analysis using the Newman-Keuls method disclosed that, in all cases, these temporal means differed significantly from one another (table 1).

ANALYSIS COMPARING NUMBER OF HOURS OF SPORTS INVOLVEMENT AND OUTCOME VARIABLES

Correlations were undertaken between number of hours of sport and exercise involvement before injury and the following potential confounders: age, physiotherapist rated patient injury severity, and length of formalised rehabilitation. A negative association was observed between age and the weekly time invested in sport and exercise (r(92) = −0.28, p<0.01); as would be expected, younger participants were more involved. No other significant correlations emerged. In addition, analysis of variance showed that significant differences between men and women with respect to the number of hours of sport and exercise involvement. Accordingly, subsequent analysis was by partial correlation controlling for age.

The only significant relations to emerge between sports and exercise involvement and the outcome variables, using the more stringent p<0.01 criterion, were between number of hours of sport and exercise involvement and confusion at time 2 (r(87) = 0.27, p<0.01) and time 3 (r(87) = 0.29, p<0.01), and perceived recovery at time 3 (r(87) = 0.27, p<0.01). Athletes who were more involved were more confused in the middle and at the end of rehabilitation, and perceived their recovery to be less at the end of rehabilitation.
ANALYSIS COMPARING THE HIGHEST AND LOWEST QUARTILES BASED ON NUMBER OF HOURS OF SPORTS PARTICIPATION A WEEK. The analysis reported so far may not have captured the particular adjustments to injury of highly committed sports people, as it treated sports and exercise involvement as a continuous variable. Accordingly, further analysis was conducted comparing the highest and lowest quartiles of involvement. The lowest quartile consisted of 23 people who exercised for one hour or less a week, whereas the 22 in the highest quartile dedicated eight hours or more a week to sport and exercise. One way analysis of variance was used to compare the lowest and highest quartile with respect to the previously identified potential confounders: age, physiotherapist rated and patient rated severity, and length of formalised rehabilitation. As may be expected, a significant group difference emerged for age \( F(1,43) = 9.43, p<0.01 \); those who invested eight hours or more a week were significantly younger (31.95 years) than those who invested one hour or less (43.83 years). A \( \chi^2 \) test comparing the number of men and women in each group was not significant.

Two factor analysis of covariance (groups, time), with age as a covariate, was used to compare the lowest and highest quartiles on the outcome measures. Largely in line with the outcome of the previously reported correlational analysis, the only significant groups main effect to emerge was for confusion \( F(1,41) = 9.39, p<0.01 \); the high participation quartile were more confused than the low participation quartile. All variables changed significantly over time, in accordance with the temporal pattern reported earlier, and no significant groups × time interactions were found.

Discussion
In line with previous research, injury had discernable emotional effects, and the negative emotional impact of injury diminished over the course of rehabilitation as self rated recovery improved. The average estimates of recovery by participants at time 1, 2, and 3 corresponded to about 40%, 60%, and 80% of rehabilitation, and mean physiotherapist rated recovery scores were about 30%, 60%, and 80% of rehabilitation. These data provide confirmation that assessments were, as planned, undertaken at approximately the beginning, middle, and end of rehabilitation. It is worth noting here that discharge occurs not at 100% recovery but at just under 80%.

It was hypothesised that those who were more involved in sport before injury would exhibit a greater emotional response to injury and perceive their recovery to be less. Only confusion and recovery were associated with the number of hours of sports and exercise involvement; those more involved in sport before injury were more confused at the middle and end of rehabilitation, and perceived their recovery to be less by the end of formal rehabilitation.

The only published study that has explicitly explored the relation between number of hours of sports involvement a week before injury and emotional responses reported no significant relation between hours of sports involvement and any of the POMS emotions, although they did report a weak relation between hours of sports involvement and anger. Number of hours of sports involvement before injury was, in line with current findings, significantly related to age, with younger participants being more involved. However, age and anger were also correlated, thus it is possible that the putative relation between sports involvement and anger was a statistical artefact which arose from their common association with age. Accordingly, there is a precedent for the present failure to find widespread associations between the affective impact of injury and athletic status.

With regard to the association between sports involvement and confusion, those more involved in sport may have had greater information needs than those less involved, and experienced confusion when such needs were not met. Those more involved in sport and exercise may require more information about alternative activities to help maintain aerobic fitness. Similarly, they may require more rehabilitation specific information in order to regain their previous high level of physical functioning; highly committed athletes may be more confused at the end of rehabilitation because they know that they are still a long way from attaining the status they had before injury. This is supported in this study by the finding that those more involved in sport perceived their recovery to be less at the end of rehabilitation, compared with those less involved.

From a practical point of view, the present results suggest that, relative to injured non-athletes, injured athletes perceived a greater mismatch between current physical status and that before injury. It is possible that physiotherapists require training in order to appreciate more fully the information needs of the highly involved athlete. Researchers have increasingly acknowledged that the physiotherapist is ideally placed to provide psychological support to injured athletes. However, several studies have found that sports injury rehabilitation personnel would prefer a greater emphasis on psychological factors in their professional training.

Recent work in Australia has resulted in a proposed psychoeducational curriculum for the training of sports injury rehabilitation personnel. The professional training of sports injury rehabilitation personnel in the United Kingdom does not routinely include the level of training proposed in the Australian psychoeducational curriculum; although cultural differences must be acknowledged, the Australian prototype may offer a useful framework for future work in the United Kingdom.

This study is arguably more wide ranging than previous studies of injured athletes. It is the first substantial study to include, as a control, people who were relatively uninvolved in sport and exercise. However, as with any study, it is not without shortcomings. Firstly, a number of authors have suggested that the POMS may not adequately reflect our mood.
state and that it may be more appropriate in future quantitative work to use the PANAS scale. 31

Secondly, as with any quantitative research, this study may be criticised for producing a somewhat fragmented and imprisoned representation of the injury experience. Further qualitative work is needed to include the subjective experiences of the injured athlete. This would permit a more detailed insight into the way patients appraise the injury episode and the emotions experienced. Both qualitative and quantitative research exploring potentially more subtle differences between the psychological reactions to chronic versus acute injuries may prove particularly illuminating.

In conclusion, the consistent findings relating to confusion and perceived recovery reinforce the importance of assessing reactions to re-entry. Recent qualitative findings that re-entry was often associated with fear of reinjury and loss of sports confidence 32 further underlines the need to extend assessment to the re-entry phase in future research.
