The impact of face shield use on concussions in ice hockey: a multivariate analysis

B W Benson, M S Rose, W H Meeuwisse

Objective: To identify specific risk factors for concussion severity among ice hockey players wearing full face shields compared with half face shields (visors).

Methods: A prospective cohort study was conducted during one varsity hockey season (1997–1998) with 642 male ice hockey players (median age 22 years) from 22 teams participating in the Canadian Inter-University Athletics Union. Half of the teams wore full face shields, and half wore half shields (visors) for every practice and game throughout the season. Team therapists and doctors recorded on structured forms daily injury, participation, and information on face shield use for each athlete. The main outcome measure was any traumatic brain injury requiring assessment or treatment by a team therapist or doctor, categorised by time lost from subsequent participation and compared by type of face shield worn.

Results: Players who wore half face shields missed significantly more practices and games per concussion (2.4 times) than players who wore full face shields (4.07 sessions (95% confidence interval (CI) 3.48 to 4.74) v 1.71 sessions (95% CI 1.32 to 2.18) respectively). Significantly more playing time was lost by players wearing half shields during practices and games, and did not depend on whether the athletes were forwards or defence, rookies or veterans, or whether the concussions were new or recurrent. In addition, players who wore half face shields and no mouthguards at the time of concussion missed significantly more playing time (5.57 sessions per concussion; 95% CI 4.40 to 6.95) than players who wore half shields and mouthguards (2.76 sessions per concussion; 95% CI 2.14 to 3.35). Players who wore full face shields and mouthguards at the time of concussion lost no playing time compared with 1.80 sessions lost per concussion (95% CI 1.38 to 2.34) for players wearing full face shields and no mouthguards.

Conclusions: The use of a full face shield compared with half face shield by intercollegiate ice hockey players significantly reduced the playing time lost because of concussion, suggesting that concussion severity may be reduced by the use of a full face shield.

Public and professional concern about the number and severity of concussions occurring in ice hockey is increasing. These injuries are one of the most dangerous types sustained in sport and therefore prevention is of paramount importance.1 Hockey associations worldwide have tried to reduce the incidence of head injuries through strict rule enforcement and by making the use of helmets and face shields mandatory.2,3 However, despite such efforts, concussions remain one of the most common types of injury sustained in this sport.4–10

Concussion has been defined as a trauma induced alteration in mental status that may or may not involve loss of consciousness.11–13 The terms concussion and traumatic brain injury are used interchangeably in this paper, as is consistent with the medical literature.14 It has been estimated that 1.5–2 million new cases of traumatic brain injury occur annually in the United States, with more than 300,000 occurring in sport.5,15 Although alarming, this figure may be an underestimation because the side effects associated with milder forms of concussion are generally transient and therefore may go unnoticed by doctors, trainers, therapists, coaches, and parents. Furthermore, many sports participants themselves are unaware that repeated minor head injuries may be unresponsive to medical treatment and cause cumulative brain damage.11–13 Therefore athletes may be reluctant to report such injuries to trainers or medical personnel.

Sport related concussions are a distinct clinical subset of traumatic brain injury because they are often witnessed and not usually associated with other injury. More than 90% of these injuries are of mild severity characterised by transient confusion, brief amnesia, and no loss of consciousness.12 Thus it is possible for an athlete to be concussed and still continue to play. Also, management decisions are easily influenced by an athlete's desire to return to competition and a coach's will to win.12 Although some traumatic brain injuries are more severe than others, none are trivial, and each has the potential to be lethal.14

Although extensive research of traumatic brain injury has provided some understanding of the biomechanics and pathophysiology of injury, specific risk factors for sport related concussions are poorly delineated and rarely studied, leaving large gaps in the knowledge of appropriate prevention strategies.1–10 Until recently, there was speculation that the added mass and area of a helmet and full face shield may increase the rotational acceleration of a player's head following impact, producing greater neuronal shearing forces and increased concussion severity.15 However, one of our studies showed that concussion severity may actually be greater for athletes wearing half shields than for those wearing full face shields because these players missed significantly more practices and games due to concussion.16 To our knowledge, no research has been conducted to identify risk factors that may increase concussion severity associated with the use of different types of facial protection.

The purpose of this study was to identify specific risk factors associated with increased concussion severity among ice hockey players wearing full face shields compared with half face shields.
METHODS
A more detailed description of the methods has been previously published. This prospective cohort study was conducted during the 1997–1998 Canadian Inter-University Athletics Union (CIAU) hockey season. The CIAU is a national league consisting of four divisions with identical officiating and player eligibility rules except that each division mandates the use of protective equipment. The Ontario Universities Athletic Association (OUAA) requires all athletes under its jurisdiction to wear full face shields for every practice and game throughout the varsity season. In contrast, the Canada West Universities Athletic Association (CWUAA) and Atlantic Universities Athletic Association (AUAA) mandate all athletes to wear at the very least half shields (visors) for all practices and games. For this study, two cohorts were defined by their exposure to mandated facial protection.

Subjects and data collection
The study population included 642 male ice hockey players from 11 CIAU teams competing in the OUAA, seven teams in the CWUAA, and four teams in the AUAA. Thus athletes from the 11 OUAA and 11 CWUAA/AUAA teams formed the cohorts wearing full face shields and half face shields respectively.

Approved by the bioethics committee of the University of Calgary, this study required team therapists to obtain informed verbal consent from all players before participation. Previous injury status was documented for each CWUAA player using a standardised medical form during a mandatory pre-season medical examination with the team doctor. Because team doctors of institutions participating in the OUAA and AUAA did not uniformly use standardised forms, athletes competing in these divisions completed an injury history questionnaire with their team therapist during a preseason meeting. The injury information recorded on these forms served as a baseline for the 1997–1998 hockey season. From the first organised practice of the season, team therapists recorded the level of individual participation (full, partial, or none) and the type of face shield worn for every practice and game throughout the season. If a player sustained an injury that met the reportable injury definition, team therapists, doctors, or both were required to complete an injury report form. The athlete participation forms were designed so that it could be determined (on a daily basis) which injury resulted in time lost from participation as 1, a partially missed session as 0.5, and a completely missed session as 0. For example, 25 athletes fully participating in 10 games would yield 250 game athlete exposures. Information on goaltender exposure and injury was not included in the analyses so that a true comparison could be made between players wearing full face shields and those wearing half face shields. In addition, several potential risk factors for concussion severity were assessed, including injury setting (game v practice), position (forward v defence), previous concussion status (new v recurrent), and experience level (rookie v veteran). Concussion severity associated with mouthguard use (both commercial and custom fitted by dentists) was assessed independently for each cohort. An analytical comparison was not conducted because individual exposure information on mouthguard use was not collected by the therapists, and athletes from the half shield cohort had division rules in place that mandated the use of mouthguards, while no such rules were in effect for the cohort wearing full face shields.

The sample size of this study (642) was chosen from a previous investigation. Based on the finding that concussions accounted for about 16% of the total reported injuries sustained by players wearing full face shields and using a two sided test (α = 0.05, β = 0.20), it was estimated that 258 subjects in each group (n = 516) would be required in this study to achieve 80% power to detect a relative risk of 2.0 or more between the two study groups. StaCalQuest 4 (Belmont, California, USA) was used to calculate Poisson confidence intervals for the playing time lost per concussion.

RESULTS
Athlete characteristics
All 642 varsity athletes from the 22 participating teams consented to have data collected and sent to the CISIR. Athlete exposure (participation) information was 100% complete throughout the 1997–1998 hockey season, and all but one injury report form involving time loss from participation was sent to the CISIR (99.9% completion rate). It was not possible to determine the completion rate for injuries that did not result in time lost from participation.

Table 1 provides a descriptive comparison of the two study groups. Of note, 11.9% and 9% of athletes competing in the full and half shield divisions respectively did not have medical forms or injury history questionnaires returned to the central registry. These players participated for only a minimum duration of time on a varsity team or joined a team later in the season.

Concussion incidence
Forty one concussions were sustained by players wearing half face shields during the 1997–1998 season compared with 38 by players wearing full face shields at the time of injury. The incidence of concussion in Canadian intercollegiate ice hockey was 1.35 per 1000 athlete exposures. Based on the absolute number of concussions sustained by players from both cohorts during the 1997–1998 season (n = 79), we can expect to see an

</table>
average of three to four concussions per team during any given season. The overall risk of sustaining a concussion was not significantly different for players wearing half shields compared with those who wore full facial protection at the time of injury (p = 0.90).

Most concussions sustained by players in both study groups occurred during regular season play (full shield, 27; half shield, 26), followed by exhibition season (full shield, 7; half shield, 6), and playoffs (full shield, 4; half shield, 2). All 38 concussions sustained by players competing in the full shield division occurred during organized games (13 home games, 21 away games), compared with 34 of the 41 concussions sustained by athletes competing in the half shield divisions (9 home games, 24 away games). Most of the game concussions occurred in the second period (full shield, 16; half shield, 14), followed by the third (full shield, 10; half shield, 11) and first periods (full shield, 8; half shield, 8). For players in the full shield division, the period of injury was not reported on three injury report forms, and the game setting was not reported on four forms. In the half shield divisions, game setting and period of injury were not recorded on one injury report form.

A χ² analysis of the data showed a non-significant difference between the two groups for season of injury (p = 0.76), period of concussion (p = 0.92), and game setting—that is, home vs away (p = 0.34).

Table 2 highlights the mechanism of concussions sustained by players from the two study groups and the subsequent playing time lost from games and practices. Direct player contact was the predominant mechanism of injury for athletes wearing half shields resulting in an average of 4.85 games and practices lost per concussion. In comparison, contact with the boards, plexiglas, or net following a body check caused most concussions among athletes wearing full face shields resulting in an average of 1.35 sessions lost per concussion.

Table 3 highlights the severity of concussions sustained by players from the two study groups, as measured in time lost from practices and games (sessions). The playing time lost per concussion for players wearing half shields at the time of injury was significantly more than for players who wore full face shields at the time of injury (1.71 sessions per concussion; 95% CI 1.32 to 2.18). The playing time lost per concussion sustained during a game was significantly greater for players who wore half face shields (3.29 sessions lost per concussion; 95% CI 2.71 to 3.96) compared with full face shields (1.70 sessions lost per concussion; 95% CI 1.32 to 2.18). No athletes sustained concussions during practices while wearing a full face shield compared with seven athletes (54.5 sessions lost) who wore half face shields at the time of concussion.

Concussion severity

Table 3 highlights the severity of concussions sustained by players from the two study groups based on the amount of time lost from competition. Twenty-five athletes who sustained concussions from the full shield division missed less than one full game or practice (mild severity) because of a concussion compared with 17 athletes from the half shield divisions. Twelve athletes wearing full face shields at the time of injury missed between one and seven sessions (moderate severity) compared with 17 players who wore half face shields at the time of concussion. Only one player wearing a full face shield missed more than seven sessions (severe concussion) compared with seven players who wore half face shields at the time of injury. In addition, five players in the half shield cohort who lost consciousness were immediately transferred to the hospital, compared with three players (one of whom lost consciousness) in the full face shield cohort.
have medical forms returned to the CISIR, it was not possible to
determine whether these athletes sustained a new or recur-
rent concussion. Thus the stratum specific rates of time loss
for concussion for players wearing half shields were under-
estimated.

Both forwards and defence who were concussed while
wearing a half shield missed significantly more practices and
games per concussion than those who wore full face shields at
the time of injury (forwards, 2.54 times more sessions lost per
concussion; defence, 2.34 times more sessions lost per concus-
sion). In addition, rookies and veterans who wore half shields
at the time of injury missed at least 2.83 times and 1.59 times
more sessions per concussion respectively than those who
wore full face shields at the time of concussion. Two athletes
who wore half shields at the time of concussion (48.5 sessions
lost) did not have medical forms returned to the CISIR, and
therefore the time loss rates for experience level for players
wearing half shields were underestimated.

Twenty three players who wore mouthguards and half face
shields at the time of concussion missed 2.76 sessions per
concussion (95% CI 2.14 to 3.35) compared with 5.57 sessions
per concussion (95% CI 4.40 to 6.95) among 14 players wear-
ing half face shields and no mouthguards. Two players who
wore full face shields and mouthguards at the time of concus-
sion did not miss any playing time (0 sessions per concussion;
one sided 97.5% CI 0 to 1.84) compared with 1.80 sessions per
concussion among 32 players wearing full face shields and no
mouthguards (95% CI 1.38 to 2.34). Of note, it was not known
whether a mouthguard was worn at the time of concussion for
four players competing in the half shield divisions (25.0 sessions
lost) and four players competing in the full shield division (7.0 sessions lost).

**DISCUSSION**

Sport related concussion is of major public health
significance. These injuries are the predominant reason for
hospital admission after trauma and, although rare, cata-
strophic outcomes have been reported in the literature. In
addition, concussions often occur in sporting competitions
where no medical personnel are readily available to treat
them. This puts athletes at increased risk because complica-
tions may develop that require neurosurgical care, and early
management is essential for limiting catastrophic outcome.
Furthermore there is evidence to suggest that
cumulative brain damage is associated with repeated concus-
sions; many athletes who sustain these injuries have
persistent symptoms or neuropsychological deficits that result
in social dysfunction, lost productivity, and excessive health-
care costs.

Several strategies for concussion risk management have
been proposed to date, including use of mouthguards, con-
ditioning of neck musculature, use of properly fitted and
maintained helmets, strict enforcement of rules, stiffer penal-
ties for illegal play, enhanced coaching techniques, and
improved medical care, including on field recognition and
treatment. None of these strategies, however, has been
uniformly implemented by hockey associations, primarily
because of a lack of scientific evidence to support their effec-
tiveness in reducing the incidence of concussion. Recurrent
problems that surface in the literature with respect to the
study of sport related concussion include: (a) reporting and
memory biases associated with retrospective designs; (b) lack
of uniformity in the definition of injury; (c) lack of data on the
population at risk of injury; and (d) unknown validity of the
recording mechanisms.

This study is unique in that it prospectively evaluated risk
factors for concussion severity in a natural experimental
setting using two cohorts who differed only in their exposure
to face shield use. Players from the two study groups
competed during the same time periods and were similar with
respect to age, experience level, previous injury status, and
skill level. In addition, the data were collected using a
previously validated system of injury surveillance and were
nearly 100% complete.

Misclassification or information bias results from system-
tic differences in the way data on exposure or outcome are
obtained from the various study groups. There was potential
for non-differential misclassification injury reporting bias in
this study as there was no method of verifying the complete-
ness of reporting for injuries resulting in no time lost from
participation. However, it was assumed that all concussions
were reported because the data were gathered by athletic
therapists and team doctors, who were front line healthcare
professionals during every practice and game and had the
highest likelihood of observing a concussion as it occurred.
Also the increased national and international attention of
sport related concussions would have heightened players’
awareness of the risks and increased their likelihood of
reporting these injuries to medical personnel. In addition, it
was possible that team therapists and doctors differed in their
thresholds to allow a player to return to competition after a
concussion. However, the probability that the 11 OWAA team
therapists and doctors were systematically more “conserva-
tive” in managing concussions than the 11 CWUAA/AUAA
therapists and doctors was highly unlikely. Also there was no
clustering of concussions on any one particular team within
either cohort, and the concussion playing time lost within the
half shield cohort did not differ significantly between the

mechanisms of concussion for players wearing both full face plexiglas, or net after a body check were the top two blow to an exposed jaw. The extent than would be transmitted to the brain from a direct severity among players wearing full face shields is that the full explanation for the overall observed reduction in concussion tal and concussion injury rates by 70% and 75% respectively.mine players' risk of sustaining a concussion associated with concussion severity. The met is tipped back in this position, the protective effect of the helmet and half shield unit so that the visor extends down to their eyes in order to get a clearer view of the play. If the hel-practices are given the freedom to wear their helmets during games, a penalty is given to any player who does not fasten his chinstrap or who does not wear his helmet and half shield units properly. During games, a penalty is given to any player who does not fasten his chinstrap or who does not wear his helmet and half shield unit so that the visor extends down to the tip of his nose. Therefore athletes who wear half shields during practices are given the freedom to wear their helmets in a manner such that the visors are raised above the level of their eyes in order to get a clearer view of the play. If the hel-shoulder during impact, thereby maintaining maximum protection from concussion. Another possible explanation for the overall observed reduction in concussion severity among players wearing full face shields is that the full shield helps to disperse and absorb impact forces to a greater extent than would be transmitted to the brain from a direct blow to an exposed jaw.

Thirdly, direct player contact and contact with the boards, puck, or net after a body check were the top two mechanisms of concussion for players wearing both full face shields and half shields. These mechanisms are considered by many to be an inherent part of the game. However, referees must be vigilant for checking from behind, elbowing, cross checking, and high sticking, all of which were shown to be common types of illegal play causing concussion in this study. Furthermore, referees must not alter the way in which they “police” the game with the evolution of improved protective equipment, especially in leagues that mandate full face shield use where the consequences of illegal play—for example, facial lacerations, dental fractures, etc.—are not as evident.

In reality, it is impossible to avoid all risk in sport. The probability that one piece of protective equipment can prevent 100% of the injuries to its intended anatomic region is low. This is especially true in ice hockey, which has many inherent features that predispose players to injury, including high acceleration-deceleration, rapidly changing directions, shooting, body checking, and a low friction ice surface. These characteristics result in frequent collisions between players and forceful impacts with the side boards, goal posts, pucks, and hockey sticks. The goal then is to avoid unnecessary foreseeable risk and try to control that which is understood to be inherent to the sport.

Finally, these findings are based on data from adult collegiate hockey players and may not be generalisable to high school and younger skeletally immature players. In this study the use of full face shields was associated with significantly less loss of playing time because of concussion as compared with half face shields. This finding supports the suggestion that half shield use may be a specific risk factor for increased concussion severity. Athletes must be educated about the risks of concussion and encouraged to wear full face shields and mouthguards in practices and games to reduce the risk of long term disability associated with concussion.

Concussion is a significant problem in ice hockey at all levels, from youth to professional. It is critical that research be carried out to look at ways to reduce the risk and severity of this potentially devastating injury. It is well accepted that full facial protection has virtually eliminated facial injury in hockey. A popular “myth” was that wearing increased facial protection may actually increase injury incidence and severity, because of the increased weight of the facial protection, inability to see as well, and more rough play when players feel more protected. The authors’ previous study showed clearly that this was not the case. This study looks further into one of the first study’s observations, and shows that concussion severity is also reduced by full facial protection. It also suggests that style of play and rule enforcement are important factors in reducing concussion risk. Mouthguards are a more controversial issue; while there appeared to be a protective effect from mouthguards in terms of time lost because of concussion, the numbers in the study were small. More research is needed to determine the effect of mouth guards in reducing concussion risk and severity, not only in hockey, but in all sports.

COMMENTARY

This study gives the ice hockey community an immediate solution to the severity of concussion in players beyond strict enforcement of the rules and player to player respect. Although the incidence of concussion will only decrease if the heavy hitting and illegal hitting is decreased, the full shield and the mouthguard offer the opportunity to reduce the severity of concussion which may decrease the cumulative effect of repeated concussions.

A tag on to this study, the effect of wearing a mouthguard on the severity of concussion, is significant because it supports the use of mouthguards to reduce concussion injury. In the early 1960s, when the mouthguard was made mandatory in American football, the medical staff at Notre Dame reported a 50% reduction in concussion in the first season. Players should be fitted for mouthguards and be required to use them during practice and competition, and officials should make the penalty call when the mouthguard is not properly used.
