Mutations in the hereditary haemochromatosis gene HFE in professional endurance athletes

J L Chicharro, J Hoyos, F Gómez-Gallego, J G Villa, F Bandrés, P Celaya, F Jiménez, J M Alonso, A Córdova, A Lucia

Background: Hereditary haemochromatosis, a disease that affects iron metabolism, progresses with a greater or lesser tendency to induce iron overload, possibly leading to severe organ dysfunction. Most elite endurance athletes take iron supplements during their active sporting life, which could aggravate this condition.

Objective: To determine the prevalence and discuss potential clinical implications of mutations of HFE (the gene responsible for hereditary haemochromatosis) in endurance athletes.

Methods: Basal concentrations of iron, ferritin, and transferrin and transferrin saturation were determined in the period before competition in 65 highly trained athletes. Possible mutations in the HFE gene were evaluated in each subject by extracting genomic DNA from peripheral blood. The restriction enzymes SnaB1 and BclI were used to detect the mutations 845G→A (C282Y) and 187C→G (H63D).

Results: Our findings indicate a high prevalence of HFE gene mutations in this population (49.2%) compared with sedentary controls (33.5%). No association was detected in the athletes between mutations and blood iron markers.

Conclusions: The findings support the need to assess regularly iron stores in elite endurance athletes.

ORIGINAL ARTICLE

H
ereditary haemochromatosis is an autosomal recessive disease in which the body’s iron stores are increased, with serious negative effects on the function of several organs (liver cirrhosis, diabetes mellitus, heart failure). The clinical consequences of iron overload in these patients can be prevented by early diagnosis and appropriate treatment.

The HFE gene plays a major role in hereditary haemochromatosis. It occurs in the short arm of chromosome 6. Most patients with manifest hereditary haemochromatosis are homozygous for the C282Y mutation, and a small proportion are heterozygous for both the C282Y and H63D mutation of the HFE gene. Only a few affected cases show C282Y heterozygosity or H63D homozygosity. Subjects with these two genotypes generally display fewer markers of iron overload than C282Y homozygotes. Although these patients have a very low or no risk of developing cirrhosis or other complications, some authors suggest that they should be treated similarly to C282Y homozygotes. Moreover, despite the compound C282Y/H63D heterozygous defect expressing the disease with low penetrance (0.44–1.5%), it has been identified as an independent risk factor of death from cardiovascular causes or myocardial infarction.

There is considerable evidence to suggest that mutations in the HFE gene, even H63D heterozygosity, affect blood iron indices, and subjects with one or more mutations show higher blood iron concentrations and transferrin saturation than subjects without mutations. Deugnier et al. recently explored factors that induce the increased iron reserves observed in elite cyclists, and suggested that increased serum ferritin was mainly related to the excessive iron supplements taken by these athletes rather than to mutations in the HFE gene (C282Y and H63D).

Despite the tremendous advances made in the area of genetic mutations in disease since 1996, genetic evaluations such as screening the general population are not recommended. Phenotypic analysis based on transferrin saturation still seems to be the best and most economical diagnostic method to either preclude or warrant a more in-depth analysis of the disease in a particular subject. Thus, if transferrin saturation is >45%, a genetic analysis of HFE mutations and serum ferritin determination would be called for, to better estimate the subject’s iron stores.

This study was designed to evaluate the prevalence of HFE mutations in elite endurance athletes. The results were compared with those of a control group matched by region of origin.

MATERIALS AND METHODS

Subjects
Sixty five elite, male athletes (50 professional road cyclists and 15 Olympic class endurance runners) from Spain were enrolled in the study. Written consent was obtained from each subject according to the guidelines of the Universidad Complutense, Madrid.

The mean (SD) age, height, mass, and maximum oxygen consumption ($V_{O2\text{max}}$) of the athletes were: 26 (3) years, 178 (5) cm, 66.7 (6.1) kg, and 71.8 (7) ml/kg/min respectively. The subjects were previously confirmed to be healthy by a medical examination including electrocardiography and cardiac ultrasonography. No subject had a familial or personal history of endocrine or metabolic disease. No exogenous substances had ever been detected in anti-doping checks performed in the subjects by the corresponding official organisations. Most (90%) of the athletes took iron supplements (not including the C282Y/H63D heterozygous subject (see the Results section)) at a mean dose of 105 mg Fe on alternate days for at least six months of the year. Doses and treatment regimens were similar in each subject.

A control group (n = 134) composed of random sedentary men from Spain also entered the study.

Measurement of blood iron markers in the athletes
Fasting blood samples were collected from all the athletes after at least three rest days during the period before competition. When available, serum ferritin concentrations
Study of C282Y and H63D mutations in all subjects
Genomic DNA was extracted from peripheral blood using a standard phenol/chloroform procedure followed by alcohol precipitation. DNA amplification was performed using polymerase chain reaction (PCR) with specific primers for the two HFE gene mutations as described previously. The PCR conditions for both mutations were as follows: initial denaturation at 95°C for five minutes; 35 cycles at 95°C for one minute, 55°C for 45 seconds, 72°C for one minute, and a final extension at 72°C for five minutes. The PCR products were then subjected to enzymic digestion for two hours, with restriction endonucleases cleaving the DNA at specific points such that the presence or absence of the mutations could be detected. The restriction enzymes used were SmalI for the 845G→A (C282Y) mutation and BclI for the 187C→G (H63D) mutation. The digested fragments were visualised by electrophoresis on 2% agarose gels stained with ethidium bromide (fig 1).

Statistical analysis
All variables were tested for normality. We compared the distribution of HFE genotypes in both athlete and control groups with the Fisher exact test. Ferritin data for athletes were log transformed to normalise the distribution before analysis. Differences between genotypes in the athlete group were identified by one way analysis of variance. In this group, the paired t test was used to compare the variables according to the presence or lack of mutations. Correlation between paired quantitative data was assessed by the Spearman test. All statistical analyses were performed using SPSS 9.0 software for Windows. The level of significance was set at 0.05.

RESULTS
Table 1 shows the prevalence of the different HFE gene mutations in the two groups. The proportion of subjects without a HFE gene mutation was significantly higher in the control group than in the athlete group (66.5% vs 50.8%; p = 0.03). H63D heterozygosity occurred in 41.5% of the athletes and 24.6% of the controls (p = 0.01). No other significant difference was found between groups. No homozygote for the C282Y mutation was detected in athletes or controls.

Table 2 shows biometric variables, maximum aerobic capacity, and blood iron markers in subgroups of athletes established according to the type of HFE mutation carried. No significant differences in any of the variables (p>0.05) were detected among subgroups. The different variables were also compared in the athlete group in terms of the presence or absence of mutations (table 3). No differences were observed among the subgroups.

DISCUSSION
The most important finding of our study was the high proportion of endurance athletes with a mutation in the HFE gene (49.2%), 29 (44.6%) of whom carried an H63D mutation and three (4.6%) a C282Y mutation. The prevalence of H63D heterozygosity was significantly higher (p = 0.01) than in controls (41.5% vs 24.6%). Our results are in agreement with those of previous research showing that in the general population of Spain the prevalence of the H63D mutation ranges from 16%20 to 30.4%,21 and C282Y mutations occur in 2%20 to 4.4% depending in both cases on the geographical region.22 Thus, the prevalence observed here (especially for H63D) is much higher than that previously reported in non-athletic subjects, yet is similar to rates recently observed by Deugnier et al.,15 who also warned of a higher prevalence of H63D mutations in French cyclists compared with healthy controls. It remains to be seen if these mutations afford any metabolic advantage to these athletes during exertion. We detected no significant differences in \( V_{\text{O2\,MAX}} \) between subjects with or without the mutation, thus we cannot confirm this hypothesis.

Although there appeared to be no relation in the athlete group between the presence and absence of mutation with respect to the blood iron markers, it is observed that 61.1% of

athletes with high ferritin concentrations had a mutated HFE gene. It is known that long term exposure to small amounts of iron can lead to atherogenesis and ischaemia/reperfusion damage caused by free radical formation.\textsuperscript{24} Even minimally increased iron deposits in people heterozygous for the mutations could be detrimental and enhance the risk of cardiovascular disease.\textsuperscript{24} Thus, taken together, our findings suggest that the prevalence of HFE gene mutations is high among elite endurance athletes (runners and professional cyclists). Regular determination of their iron reserves is recommended to prevent iatrogenic iron overload.

Cardiovascular stress on an experienced elite basketball referee during neonatal competition

A S Leicht

This case report examined the cardiovascular stress imposed on an experienced elite basketball referee during national competition. The average heart rate was similar for all matches, approximated 73% of maximum heart rate, and was experienced for most (>63%) of the match. Similar relative exercise intensity was demonstrated regardless of match play (men’s v women’s) and officiating type (two v three-referee). Further study is needed to document the physiological characteristics of elite basketball referees for greater performance.

An unusual presentation of immersion foot

D M MacGregor

We report a case of “green foot” in a child with a plaster cast applied for a fractured metatarsal who subsequently represented with circulatory compromise. The foot was green and smelly and profuse Pseudomonas aeruginosa was cultured. The infection cleared with simple exposure to air. Perhaps this diagnosis should be considered in patients presenting with circulatory compromise in a cast as severe infection can result in amputation.

Sodium ingestion and the prevention of hyponatraemia during exercise

The study of Twerenbold et al.1 is important for a number of reasons, not all of which may have been emphasised sufficiently by the authors. Firstly, it confirms that a rate of fluid intake of 1000 ml/h is too high for a group of female runners running at ~10 km/h and who would therefore complete a 42 km marathon in about 4.25 hours. As the athletes drank 4 litres and gained 2 kg during the trial, their average rate of weight loss (as opposed to sweat rate) was about 500 ml/h. As not all of the weight lost during exercise is sweat and as much as 1–3 kg of this weight loss may result from fuel and water losses that do not contribute to dehydration,2–3 the absolute maximum rate at which these athletes should have ingested fluid during exercise was probably even less than 500 ml/h. This is substantially less than the drinking guidelines of the American College of Sports Medicine4–5 and the Gatorade Sports Science Institute6 and the recent recommendations by the American College of Sports Medicine and the American Medical Directors Association.7–8 The guidelines of the American College of Sports Medicine and the American Medical Directors Association equate to a quite reasonable sweat [Na+] of around 200 mmol/l. It is not immediately clear why the authors chose concentration of 34 mmol/l caused hyponatraemic encephalopathy,1–2,5 it is not immediately clear why the authors chose concentration of 34 mmol/l caused hyponatraemic encephalopathy,1–2 but that finding has relevance to the sodium requirements of athletes who are specifically advised not to overdrink during exercise to ensure adequate sodium chloride intake.6

For example, the presence of a control group who drank according to the dictates of thirst (“ad libitum”) and not according to the guidelines of influential sports medical6–7 and commercial organisations, so that they may be less prone to overdrink and so to gain weight during exercise, would have established that athletes who lose more than 1–3 kg during exercise do not develop symptomatic hyponatraemic encephalopathy1–2 even though they are both dehydrated and sodium deficient. Rather, they are more likely to finish such races with raised serum sodium concentrations.9–13

I would rather argue that a fundamental feature of all prospective trials that aim to evaluate a novel intervention such as the role of sodium ingestion in the prevention of hyponatraemia during exercise should be to compare the new intervention with the currently established best practice.

As the currently established best practice is not to ingest fluid at such high rates that weight is gained during exercise, because this practice can produce a fatal outcome,9–10 so this study design should, in retrospect, not have been sanctioned. Rather, the control group in the study should have ingested fluid according to guidelines based on the strongest body of current information. It is, for obvious reasons, my biased opinion that the guidelines that come closest to a defendable evidence base are those that have been recently accepted by the United States Track and Field and the International Marathon Medical Directors Association.11–16

Fortunately the data of Twerenbold et al.1 do allow some calculations to estimate the likely value of the extra sodium that was ingested by two of their groups. Thus, the athletes in their study lost, on average, 1.8–2.1 kg of sodium during exercise, as calculated from their body weight. As the starting serum ([Na+]) in the three groups of runners was ~137 mmol/l (table 3 of their article), the average total ECF Na+ content of the three experimental groups was 1989–1993 mmol/l at the start of the race. As weights increased by 1.8–2.1 kg in the three groups during exercise (table 3 of their article), the increases in ECF volume would have been 450–525 ml in the respective groups, assuming that the ECF increased in proportion to the increase in total body weight. As the starting serum (and ECF) sodium concentration ([Na+]i) in the W group after the race would have been even lower (128 mmol/l) than that actually measured after the race (132 mmol/l; table 1). It is therefore probable that the serum [Na+] in the W group after the race was ~84 mmol/l divided by post-race serum [Na+] in mmol/l.

Indeed, if subjects in the W group did lose 34 mmol Na+ during the race but also had a post-race ECF volume expanded to 14.95 litres, then their post-race [Na+] would have been even lower (128 mmol/l) than that actually measured after the race (132 mmol/l; table 1). It is therefore probable that the serum [Na+] in the W group after the race was ~84 mmol/l. 

Unfortunately, the vital importance of these small changes in ECF volume in determining whether hyponatraemic encephalopathy will develop in those who over-drink during exercise1–2 is sometimes probably to be ignored by those1–2,11–15,20–25 who argue incorrectly that it is the Na+ deficit that determines the extent to which the serum [Na+] falls in those who develop hyponatraemia during exercise. This calculation elegantly shows why small changes in ECF volume determine whether or not hyponatraemic conditions are present. 

Providing it isn’t libellous or obscene, it will be posted within seven days. You can email by clicking on “eLetters” submit a response by clicking on “read eLetters” on our homepage.

encephalopathy will develop in those who overdrink, regardless of whether or not they also incur a Na" deficit either during exercise or at rest. A recent paper confirms this prediction by showing that mathematical modelling supports the argument that changes in TBW exert a much greater effect on serum [Na" ] than does whole body Na" content in those who overdrink and hence gain weight during exercise. Perhaps the point of these calculations is to show that it is not possible to calculate the state of Na" balance in athletes during exercise and so to determine whether or not athletes have developed a Na" "deficit," simply by measuring serum [Na" ] This is because the ECF volume will not be the same before, during, and after exercise and will change depending on the nature of the fluid ingested and the extent of any fluid deficit or excess that develops during exercise. But more importantly, these calculations clearly show why the regulation of the TBW and the ECF volume will have a much greater influence on serum [Na" ] than will either the expected Na" losses in sweat or the amount of Na" ingested from sodium-containing sports drinks.

For example a 1 litre (7%) reduction in the ECF volume would "release" 140 mmol Na" into the contracted ECF volume. This means that it is possible to lose 140 mmol Na" in sweat and urine without any change in the ECF volume and the extent of any fluid deficit or excess that develops during exercise.

In summary, these calculations explain why contraction of the ECF in athletes who lose body weight during exercise will maintain the serum [Na" ] even in the face of quite large and unreplaced Na" loss in sweat, and why the ingestion of sodium-containing sports drinks in the vain hope of matching the rates of Na" loss in sweat can only lead to fluid retention and progressive hyponatraemia, as elegantly shown by this study. Indeed if this inappropriate behaviour is approached with sufficient vigour, ultimately the result will be death from hyponatraemic encephalopathy, which, as these calculations and this study again show, cannot occur without the presence of distinct fluid overload.

Finally, it is important to note that, even though Na" ingestion marginally increased serum [Na" ] in the group that ingested the most concentrated Na" drink, this practice was without benefit as running performances were unaltered by Na" ingestion, and the incidence of symptoms was no different between the groups as no athletes reportedly developed symptoms. However, the symptoms of mild hyponatraemic encephalopathy are mild and may not have been sought with sufficient diligence. For example, all subjects, myself included, in our study in which mild hyponatraemia was induced by fluid overload at rest, developed quite disabling symptoms at serum [Na" ] of ~136 mmol/l or lower. Indeed it would have been most interesting to determine whether the presence of subtle mental symptoms was different in the three groups in this study, as all had similar degrees of fluid overload despite different serum [Na" ]. If the symptoms in this condition are due purely to fluid overload, then the incidence of symptoms should have been the same in all groups despite different serum [Na" ]. Alternatively, if the symptoms are related to the degree of hyponatraemia, then they should have been most obvious in the W group, who finished with the lowest post-race serum [Na" ]. My bias would be to expect that the extent of any symptoms are more likely related to the degree of fluid overload, and hence the increase in the ICF, than to the level to which the serum [Na" ] has been reduced.

BOOK REVIEWS

Tennis

It is widely recognised that each sport has its own unique demands and injuries. Therefore the IOC, IFT, ATP, WTA, and Society for Tennis Medicine and Science should be congratulated on producing, in this publication, a comprehensive overview of tennis sports medicine. Together they have assembled an impressive array of experts in this field to write succinct and relevant chapters.

Every aspect of tennis is covered to cater for a broad range of readers, including players themselves. Some areas are covered in a high level of technical detail to please the biomechanists, in particular. However, some of the sports medicine is basic in concept and lacking significant evidence based validity.

Nevertheless, I would highly recommend this book to any health professional who treats a large number of tennis players. Most chapters provide a link between common sports medicine problems and their occurrence in tennis, including conditions that are unique to this sport. At times, some authors are somewhat optimistic with their view of recovery time from surgery—for example, three weeks for arthroscopic debri-dement of the infrapatellar fat pad.

Overall it is well presented with relevant and useful photographs and diagrams to aid the reader, and each chapter gives a list of further recommended reading. Unfortunately the book does not provide an answer to where 14 million tennis balls go, imported each year into Australia, as discussed by the editor recently!

T Wood

Dying to win

Dying to win gives an eye opening account of the extent to which drugs play a major role in sport. Doping is not new and has been used in sport since ancient Olympic times; it is just that drug use in modern times is at such a level of sophistication, it is now an industry in its own right. The book describes the privileged position sport holds in society, having appeal for both the participant and the spectator. This has led to the massive media interest, commercialism, professionalism, and governmental regulation and manipulation. Economic pressure in the industrialised world and governmental propaganda in the former East Germany, and more recently China, pave the way for increasing pharmaceutical intervention in sport. With the fall of the GDR, the world saw for the first time what it had long suspected, the extent of systematic doping on a State run basis, and the most interesting fact is that the East Germans held records! Further, the book takes a look at the next big issue surrounding drugs in sport—genetic engineering.

Dying to win does not just describe the evolution of doping. It explains the complex relation between anti-doping policy, implementation of those policies, and the role of governments, the IOC, and national and international sporting organisations. With the ever increasing involvement of the legal profession, a vicious circle occurs: it becomes too costly for sporting organisations to fight court battles, with their reliance on Government funding depending on results and punishments set in accordance with what will stand up in courts. This all leads to the relative inertia of the governing bodies to be pro-active in the anti-drugs campaign. The inception of the World Anti-Doping Agency (WADA) after the 1998 Winter Olympics has provided a way forward to standardise and implement anti-doping policy across the world by an independent body.

Problems and solutions to anti-doping policy are addressed. The major problem is inadequate definition of doping—to quote Arthur Gold “The definition lies not in words but in integrity of character.” It is interesting to note that those behind the athlete, namely coaches, administrators, medical profession, and scientists, all seem to lose perspective along with their ethics and “integrity of character” when the race for “gold” is on. Dying to win suggests that these people should be held just as accountable as the athletes themselves. Another unfortunate aspect of anti-doping policy is the difficulty in detecting some abused drugs and the fact that these strategies often lag behind the ability of the pharmaceutical industry to develop new drugs, often for genuine medical reasons but with the unfortunate ability to enhance performance. Education is proposed as a key aspect to anti-doping policy, and parallels with its success in the use of recreational drugs are made. Governments also play a role in limiting supply, decreasing demand for drugs, and the implementation of independent bodies to carry outtesting. The success of anti-doping policy is also hard to measure. Fewer positive tests may simply reflect a move to less detectable methods rather than a decrease in use, and success may be better measured in terms of fewer world records.

Dying to win gives an accurate account of the problem of doping in sport and the difficulties and complexities in finding solutions to the problems. It makes interesting and provocative reading for anyone interested in sport, from the athlete and coach to the sport administrator, the medical profession, and governments.
1st World Congress on Sports Injury Prevention
23–25 June 2005, Oslo, Norway
This congress will provide the world’s leading sports medicine experts with an opportunity to present their work to an international audience made up of physicians, therapists, scientists, and coaches. The congress will present scientific information on sports injury epidemiology, risk factors, injury mechanisms and injury prevention methods with a multidisciplinary perspective. Panel discussions will conclude symposia in key areas providing recommendations to address the prevention issue in relation to particular injuries and sports.
