Effectiveness of extracorporeal shock wave therapy for tennis elbow (lateral epicondylitis)

D Stasinopoulos, M I Johnson

Randomised controlled trials were reviewed to evaluate the evidence of the effectiveness of extracorporeal shock wave therapy in the management of tennis elbow. Seven relevant trials were found, which had satisfactory methodology but conflicting results. Further research with well designed randomised control trials is needed to establish the absolute and relative effectiveness of this intervention for tennis elbow.

Lateral epicondylitis or tennis elbow is one of the most common lesions of the arm. This injury is a major challenge, as it is difficult to treat, prone to recurrence, and may last for several weeks or months, with the average duration of a typical episode reported to be between six months and two years.1

Tennis elbow is defined as pain on the facet of the lateral epicondyle, which is reproduced by digital palpation on the above site, resisted wrist extension, resisted middle finger extension, and gripping.2,4 The dominant arm is commonly affected, with a prevalence of 1–3% in the general population, but this increases to 19% in 30–60 year olds and appears to be more long standing and severe in women.2,5-8 It is generally a work related or sport related disorder of the common extensor origin of the arm, usually caused by excessive, quick, monotonous, repetitive movements of the wrist, especially in eccentric contractions and gripping activities causing macroscopic and microscopic tears in the extensor carpi radialis brevis tendon, the most commonly affected structure.3,5-12 It is a degenerative or failed healing tendon response characterised by the increased presence of fibroblasts, increased amounts of proteoglycans and glycosaminoglycans, vascular hyperplasia, and disorganised collagen in the origin of the extensor carpi radialis brevis tendon.13-19

The diagnosis is simple and confirmed by tests that can be used in daily clinical practice such as palpation on the facet of the lateral epicondyle, the Tomsen test, handgrip dynamometer testing, Mill’s test, chair test, and the coffee cup test.20-21

Although the diagnosis of this condition is simple and easy, its management is difficult. Conservative treatment is the primary choice, but a plethora of interventions, medical and physiotherapeutic with different theoretical mechanisms of action, have been reported, all with the single aim of reducing pain and improving functional status. However, such a variety of treatment options suggests that the optimal management strategy is not known, and more research to discover the most effective treatment is needed.

Extracorporeal shock wave therapy (ESWT) is a recently introduced modality for the management of tennis elbow. Its effectiveness has been evaluated in a review,27 but conclusions, positive or negative, cannot be drawn from this review because of the small number of studies included. As it is the only systematic review of the effectiveness of ESWT in the management of tennis elbow based on literature published until 2002, and several new randomised controlled trials (RCTs) have been published since then, an updated systematic review seemed to be indicated. Therefore the aim of this article was to determine the effectiveness of ESWT in the management of tennis elbow and to provide recommendations based on this evidence.

METHODS

Search strategy

Computerised searches were performed using Medline (from 1966 to August 2004), Embase (from 1988 to August 2004), Cinahl (from 1982 to August 2004), Index to Chiropractic Literature (from 1992 to August 2004), Chiroplants (from 1994 to August 2004) and SportsDiscus (from 1990 to August 2004) databases. Only English language publications were considered. The following search terms “tennis elbow”, “lateral epicondylitis”, “lateral epicondylalgia”, “rehabilitation”, “extracorporeal shock wave therapy”, “management”, “clinical trials”, and “randomised control trials” were used individually or in various combinations. Other references were identified from existing reviews and other papers cited in the publications searched. Further citations were sought from the reference sections of papers retrieved, from contacting experts in the field, and from the Cochrane Collaboration (last search July 2004), an international network of experts who search journals for relevant citations. Unpublished reports and abstracts were not considered. Keywords and search strategy were selected by the researcher only, without the help of an expert librarian with experience in searching databases to computerised health literature.

Selection of studies

To be included within the review, studies had to fulfil the following conditions: it had to be a RCT, with or without follow up, which included

Abbreviations: ESWT, extracorporeal shock wave therapy; RCT, randomised control trial
subjects aged 18 and above treated for tennis elbow. The treatment had to be any type of ESWT evaluated against at least one of the following: (a) placebo; (b) no treatment; (c) another treatment, conservative (physical therapy intervention or medical) or operative. RCTs in which the ESWT was given as part of the treatment—for example, non-steroidal anti-inflammatory drugs and ESWT or ultrasound and exercise programme and ESWT—were excluded, because we would not know how each modality contributed to the results. However, the effectiveness of these management strategies has not been assessed in the literature. Data were sought for one of the following four primary outcome measures: pain (scales or descriptive words), function (scales, tests, or descriptive words), grip strength (pain-free or maximum), and a global measure (overall improvement, proportions of patients recovered, subjective improvement of symptoms). The titles and abstracts of all studies were assessed for the above eligibility criteria. If it was absolutely clear from information provided in the title and/or abstract that the study was not relevant, it was excluded. If it was unclear from the available abstract and/or the title, the full text article was retrieved. There was no blinding to study author, place of publication, or results. The researcher assessed the content of all full text articles, making the selection criteria.

Methodological quality
The quality of the selected papers was examined using the system proposed by Chalmers et al.,28 with some minor modifications, which evaluates the design and conduct of the research by scoring the quality. According to Labelle et al.,29 it is possible to interpret the results appropriately using this system, especially when there are conflicting results. The Chalmers’ technique consists of two evaluation forms with 15 scored items, allowing a maximum score of 60. The first form examines the study design, giving particular importance to blinding of patients and doctors, and the presence and method of randomisation of the patients and doctors when applicable (table 1). The second form evaluates the quality of the data analysis, the statistical analysis, and the presentation of results (table 2).

This system has been applied to several therapeutic trials, and an arbitrary score of 70% is considered to be the minimum required for a high quality design for controlled therapeutic trials. If the score is below 40% (0–39), the design of the study is low quality, and, if it is 40–69%, it is satisfactory.29

Data abstraction
Raw data on means for all outcomes, as well as the authors’ report of the study results, were extracted from the full manuscripts by the reviewer. Data on adverse events were abstracted from the studies.

Basic data were extracted including characteristics of participants (age, sex, previous treatments, and duration of disorder), outcomes (type of outcome measure and instrument), and interventions (type, dose or intensity, frequency, and duration).

RESULTS
Trial flow
From the initial examination of citations, yielded from the literature search, 12 studies were included. After review of the completed texts, five studies were excluded,20,21,28 leaving seven eligible RCTs, to be included in the review.15–41 No additional eligible RCTs were found by screening the references.

Description of studies
Four studies35,37,38,41 explicitly excluded patients with concomitant neck, thorax, or shoulder complaints, and the rest36,39,40 excluded only patients with concomitant neck or thorax complaints.

All studies except Rompe et al.36 and Melegati et al.41 performed a short term outcome assessment (four to six weeks after the end of treatment). Five studies35,37,39,40,41 included a long term follow up (six months or more after the end of treatment).

In all studies, the study population consisted of subjects of both sexes over a wide range of ages suffering from tennis elbow.

Pain and function were the primary outcome measures for all studies. Pain was measured in all studies either by visual analogue scales, ordinal scales from 3 to 9 points, or descriptive words. Function had also been measured in all studies except those of Speed et al.36 and Crowther et al.38 either by visual analogue scales, questionnaire, or tests such as the lifting test. Other outcome measures were grip strength and global improvement or patient satisfaction. Grip strength was reported in all studies, except those of Speed et al.36, Crowther et al.38, and Melegati et al.41. Grip strength was measured as maximum grip strength36 in one study, and three studies did

DISCUSSION

In this review, the effectiveness of ESWT was assessed by searching databases in combination with reference checking for randomised controlled clinical trials. It is the first to include a satisfactory number of studies that assessed the effectiveness of ESWT in the management of tennis elbow. Conflicting results were found.

ESWT is a relatively new treatment recently introduced for managing common tendon problems such as tennis elbow with the aim to produce analgesia, although the mechanism of analgesia remains the same. It has been used for years as the standard treatment for disintegrating kidney stones. Although we found conflicting results on its effectiveness in the management of tennis elbow, it cannot be ruled out from research, as it is a dose-response modality and the optimal treatment dose has obviously not yet been discovered. It was our intention to carry this out as a dose-response analysis. However, it was difficult to test for a dose response, because of poor reporting of variables and a dearth of clinical studies comparing the effectiveness of different treatment modality variables.

Two previous systematic reviews, Smidt et al37 and Trudel et al,44 evaluated the effectiveness of physiotherapy and conservative treatments in the management of tennis elbow respectively without examining the effects of ESWT. Neither review explained why this occurred. Moreover, a systematic review of no dose response parameters was carried out in both, as we did in our review.

Although overall the quality of studies included in the review was satisfactory, there were methodological limitations. Many of the studies failed to provide adequate long term follow up, blinding, and power calculations. The use of standardised outcome measures was another area of particular deficit. Finally, the protocol of the intervention was not described in full detail, making replication difficult. Therefore well designed RCTs are needed to investigate the effectiveness of ESWT in the management of tennis elbow.

Methodological limitations of this systematic review include searching in English alone, lack of trials selection...
blinding, and absence of meta-analyses. However, information on the selection criteria is often missing from the methods section of an article, so blinding has to be broken to retrieve it, as there is evidence that a difference may exist between blinded and unblinded reviews. This is very time consuming, and the differences show little consistency in direction of bias or its magnitude. For these reasons, we decided that the reviewer should not to be blinded to the above characteristics, even though this may have increased the possibility of methodological quality and data analysis bias. Moreover, it may sometimes be difficult for reviewers to decide whether it is clinically relevant to combine the results of a group of studies in a meta-analysis—for example, studies of patients with different types of treatment, different types of comparison groups, or different clinical characteristics of patients studied. There is consensus among the editorial board of the Cochrane Back Review Group that, if relevant valid data are lacking (data are too sparse or of too low quality) or if data are statistically and clinically too heterogeneous, a meta-analysis should be avoided and reviewers should perform a qualitative review. For these reasons, a qualitative review was conducted.

Finally, we conclude that research with well designed RCTs can provide meaningful evidence on the effectiveness of ESWT for the management of tennis elbow.

**What is already known on this topic**

ESWT is a recommended treatment for tennis elbow.

**What this study adds**

The results of this review reveal conflicting findings about the effectiveness of ESWT in the management of tennis elbow. Further research with well designed RCTs is needed to establish its absolute and relative effectiveness.

**REFERENCES**

Some studies report a significant proportion of patients with ankle sprains having persistent symptoms for months or even years.

**Aims:** To determine the proportion of patients presenting to an Australian sports medicine clinic who had long term symptoms after a sports related inversion ankle sprain.

**Methods:** Consecutive patients referred to the NSW Institute of Sports Medicine from August 1999 to August 2002 with inversion ankle sprain were included. Exclusion criteria were fracture, ankle surgery, or concurrent lower limb problems. A control group, matched for age and sex, was recruited from patients attending the clinic for upper limb injuries in the same time period. Current ankle symptoms, ankle related disability, and current health status were ascertained through a structured telephone interview.

**Results:** Nineteen patients and matched controls were recruited and interviewed. The mean age in the ankle group was 20 (range 13–28). Twelve patients (63%) were male. Average follow up was 29 months. Only five (26%) ankle injured patients had recovered fully, with no pain, swelling, giving way, or weakness at follow up. None of the control group reported these symptoms (p=0.0001). Assessments of quality of life using short form-36 questionnaires (SF36) revealed a difference in the general health subscale between the two groups, favouring the control arm (p=0.05). There were no significant differences in the other SF36 subscales between the two groups.

**Conclusion:** Most patients who sustain an inversion ankle injury at sport and who were subsequently referred to a sports medicine clinic had persistent symptoms for at least two years after their injury. This reinforces the importance of prevention and early effective treatment.
