Effects of intra-session concurrent endurance and strength training sequence on aerobic performance and capacity

M Chata, K Chamari, M Chaouachi, A Chaouachi, D Koubaa, Y Feki, G P Millet, M Amri

Aim: To examine the effects of the sequencing order of individualised intermittent endurance training combined with muscular strengthening on aerobic performance and capacity.

Methods: Forty eight male sport students (mean (SD) age 21.4 (1.3) years) were divided into five homogeneous groups according to their maximal aerobic speeds ($V_{\text{O2 MAX}}$). Four groups participated in various training programmes for 12 weeks (two sessions a week) as follows: E ($n = 10$), running endurance training; S ($n = 9$), strength circuit training; E+S ($n = 10$) and S+E ($n = 10$) combined the two programmes in a different order during the same training session. Group C ($n = 9$) served as a control. All the subjects were evaluated before (T0) and after (T1) the training period using four tests: (1) a 4 km time trial running test; (2) an incremental track test to estimate $V_{\text{O2 MAX}}$; (3) a time to exhaustion test ($t_{\text{lim}}$) at 100% $V_{\text{O2 MAX}}$; (4) a maximal cycling laboratory test to assess $V_{\text{O2 MAX}}$.

Results: Training produced significant improvements in performance and aerobic capacity in the 4 km time trial with interaction effect ($p<0.001$). The improvements were significantly higher for the E+S group than for the E, S, E, and S groups: 8.6%, 5.7%, 4.7%, and 2.5% for the 4 km test ($p<0.05$); 10.4%, 8.3%, 8.2%, and 1.6% for $V_{\text{O2 MAX}}$ ($p<0.01$); 13.7%, 10.1%, 11.0%, and 6.4% for $V_{\text{O2 MAX}}$ (ml/kg/min) ($p<0.05$) respectively. Similar significant results were observed for $t_{\text{lim}}$ and the second ventilatory threshold (%$V_{\text{O2 MAX}}$).

Conclusions: Circuit training immediately after individualised endurance training in the same session (E+S) produced greater improvement in the 4 km time trial and aerobic capacity than the opposite order or each of the training programmes performed separately.

The development of the various components of muscular strength is now integrated into the training programmes of various endurance disciplines. The high level of velocity and power sustained and the imposed changes in pacing require emphasis on muscular preparation. Various studies have shown the benefit of adding strength training to improve endurance performance.

Theoretically, training induced muscle adaptations are divergent and can even be antagonistic to improvements in strength or endurance. Strength training has been reported to cause muscle fibre hypertrophy, associated with an increase in contractile protein, proportional to an increase in maximal contractile force. Strength training also reduces mitochondrial density and decreases the activity of oxidative enzymes, which can impede endurance capacity, but has minimal effect on capillary density or the conversion from fast (type II) to slow twitch (type I) fibre types.

In contrast, endurance training usually induces little or no muscle hypertrophy, but increases the mitochondrial content, citric acid enzymes, oxidative capacity, and the possibility of muscle fibre conversion from fast to slow twitch. The interference between endurance and strength training can be explained by the followings factors: (a) the inability of muscle to adapt optimally to two different stimuli because of simultaneous requests from different energy pathways during the same session; (b) muscle tiredness resulting from the preceding training; (c) the type, nature, and specific mode of strength and aerobic training; as well as the physical fitness and age of the athletes; (d) the volume, frequency, and intensity of training may also influence the degree of incompatibility observed; finally, the sequencing order—that is, the order in which endurance and strength training are carried out—may also have an effect on the training induced adaptations. However, only a few studies have reported whether strength training should precede or follow endurance training when both are performed in the same session. Previous investigations on the effects of concurrent training have used various sequences: (a) periods of several weeks of strength training before endurance training or endurance training before strength training; (b) alternating training days during the training period; (c) alternating the sequences during the training sessions. In the latter studies, aerobic capacity improved. However, to the best of our knowledge, there are no studies on the effect of the sequence order of concurrent training in the same session on endurance performance. Therefore the objectives of this study were firstly to examine the effects of concurrent strength and endurance training on aerobic performance, and secondly to determine if the order of training within the same session produces different changes in endurance performance.

METHODS

Subjects
Forty eight male sports students participated in the study. They did not do any physical activity outside of their studies (about 15 hours of multiple activities a week). All subjects gave written consent after having being informed about the study protocol, without being informed of the goal of the study. The study protocol was approved by the National University ethics committee. Anthropometric characteristics were as follows: mean (SD) age 21.4 (1.3) years; height 178.2 (5.7) cm; body mass 72.1 (6.3) kg; percentage body fat 14.7 (3.0)%. Mean (SD) aerobic maximal speed ($V_{\text{O2 MAX}}$) and maximum oxygen consumption ($V_{\text{O2 MAX}}$) were 16.16 (0.85) km/h and 50.60 (4.24) ml/kg/min respectively. The subjects were divided into five homogeneous groups according to their $V_{\text{O2 MAX}}$. 
Protocol
Four groups participated in various training programmes for 12 weeks (two sessions a week) as follows: group E (n = 10), running endurance training; group S (n = 9), strength circuit training; groups E+S (n = 10) and S+E (n = 10) combined the two training methods in different orders during the same training session. Group C (n = 9) served as a control. Before (T0, February) and after (T1, May) the training period, each subject performed the same evaluation protocol including anthropometric, field, and laboratory tests. The subjects did not perform any intense physical activity during the 24 hours preceding each test.

Physiological measurements
The subjects had field and laboratory tests during which they were greatly encouraged to reach their maximal performance. The subjects had field and laboratory tests during which they were greatly encouraged to reach their maximal performance. The speed was low at the beginning (8 km/h) and increased by 0.5 km/h each minute. The last stage reached and completed by the subject corresponded to his maximal aerobic speed (\( v_{\text{VO}_2\text{MAX}} \)), which is considered an indicator of aerobic power."

Physiological variables studied had improved significantly after 12 weeks of training. The improvements were as follows: group E+S = 8.57%; group E = 5.69%; group S+E = 4.66%; group S = 2.47%. The inter-group comparison shows that group E+S had significantly higher averaged adjusted values than the other groups (p<0.05) (fig 1).

Statistical analysis

Paired t-tests were used to determine the significance of differences in the measured variables after training. When the normality test failed, a Mann-Whitney rank sum test was performed between pre-training and post-training variables. The data were then analysed using multivariate analysis of variance with repeated measures. Because of the slight differences in the initial groups, analysis of covariance with the pre-test values as the covariate was used to determine significant differences between the post-test adjusted means in the groups. The results are presented as means (SD), p<0.05 was accepted as significant.

RESULTS

4 km time trial performance

The 4 km performance had improved significantly after training (table 2). The improvements were as follows: group E+S = 8.57%; group E = 5.69%; group S+E = 4.66%; group S = 2.47%. The inter-group comparison shows that group E+S had significantly higher averaged adjusted values than the E, S, and E groups (p<0.05) (fig 1).

Variables of aerobic capacity

The multivariate analysis of variance showed a significant interaction (p<0.001) between the two principal factors (group × time) for the maximal aerobic speed, tlim performance, VO2MAX (l/min, ml/kg/min, and ml/kg0.75/min), and the respiratory compensation threshold (ml/kg/min and %VO2MAX). After the 12 weeks of training, all physiological variables studied had improved significantly (p<0.001), except HRmax. Moreover, a significant effect of the group factor was observed (p<0.001). No changes were observed for the control group (table 2).

The univariate analysis of variance showed that training induced significant improvements in VO2MAX for the four experimental groups: 10.38% for E+S, 8.35% for E, 8.17% for S+E, and 1.61% for S. E+S had significantly higher averaged adjusted values than the other groups (p<0.01) (fig 2A).

Training induced significant improvements in tlim for the four experimental groups: 28.22% for E+S, 21.13% for E, 20.80% for S+E, and 11.28% for S. The E+S group had significantly higher averaged adjusted values than the other groups (p<0.02) (fig 2B).

Absolute (l/min) and scaled (ml/kg0.75/min) VO2MAX had improved significantly. The improvements in absolute VO2MAX (l/min) were 14.05% for E+S, 11.96% for S+E, 11.05% for E, and 8.29% for S. The improvements in scaled VO2MAX (ml/kg0.75/min) were 13.71% for E+S, 11.01% for S+E, 10.13% for E, and 6.45% for S. For absolute VO2MAX (l/min), groups E+S, E, and S+E showed comparable adjusted averaged values, whereas for scaled VO2MAX (ml/kg0.75/min),
group E+S showed significantly higher averaged adjusted values \(p<0.04\) (fig 3).

\[\text{Th2vent} \text{ increased by 21.54\% and 6.96\% for the E+S group, 14.93\% and 4.77\% for the E group, 15.99\% and 4.75\% for the S+E group, and 8.30\% and 2.26\% for the S group, when expressed in ml/kg/min or \%V\text{O}_2\text{MAX} respectively. The E+S group had significantly higher averaged adjusted values than the E (p<0.001) and S+E (p<0.03) groups.}

**DISCUSSION**

This study confirms that concurrent strength and endurance training produces improvements in aerobic capacity and endurance performance. However, the improvements are greater when, in the same session, the endurance training precedes the strength training.

**Endurance training alone**

This study confirms that intermittent sessions using running velocity close to \(v\text{V}\text{O}_2\text{MAX}\) are effective in improving aerobic power.\(^{30,31}\) These modifications are accompanied by an improvement in the 4 km test trial performance (table 2). This type of session, in which periods of high and moderate intensity are alternated, allows high intensities to be maintained for longer than a continuous training session.

**Strength training alone**

The use of short intermittent strength exercises was shown to affect aerobic capacity: the increase in \(V\text{O}_2\text{MAX}\) observed during this study was close to that noted previously (8–10%)\(^{10,12}\) but is greater than that found in other studies.\(^{5,32,33}\) The magnitude of cardiorespiratory adaptation depends primarily on the intensity, duration, and frequency of the exercise.\(^{11}\) If the intensity of work during strength training is not sufficient, oxygen consumption remains very low—that is, only 45% \(V\text{O}_2\text{MAX}.\)\(^{34}\) To reach a positive effect, it seems that a minimal level of intensity of 50% \(V\text{O}_2\text{MAX}\) has to be attained.\(^{35}\) Furthermore, the training duration was only 15 minutes three times a week. Of the other studies that did not show cardiorespiratory improvement with strength training, that of Hickson\(^{5}\) was composed of traditional strength exercises including short series (five repetitions, with heavy loads of >80% of maximum) and long (three minutes) rests. It is clear that this type of training does not fulfil the commonly acknowledged requirements of duration and intensity for endurance work. In this context, this study of strength training allowed long duration exercises which certainly helped to improve aerobic capacity. Lastly, the optimal duration for improvements in \(V\text{O}_2\text{MAX}\) with strength training has been reported to be 10–12 weeks,\(^{5,30,32,33}\) but significant improvement has also been noted with a shorter period—that is, seven weeks.\(^{35}\)
The concurrent training in this study produced significant improvements in the 4 km performance as well as aerobic capacity (table 2). This confirms the efficiency of this method in trained and non-trained subjects.1–3 12 35 93 2 These differences can be explained by the training programmes (form, intensity, frequency, and duration), the initial level, and the age and sex of the subjects. Other mechanisms may be involved, including particularly the conflict between the physiological adaptations, in addition to muscular hypertrophy which produces an increase in body mass.

Concurrent strength and endurance training
The concurrent training and cyclists may improve endurance performance by resistive weight training, because of increases in the size of type I fibres and changes in type II subtype ratios and myofibril contractile properties. These changes may allow a subject to exercise for longer at a given submaximal work rate by reducing the force contribution from each active myofibre or by using fewer myofibrils. In conjunction, the myofibre changes may also allow the recruitment of the less efficient type II fibres to be delayed.1 Hoff et al2 showed a considerable increase in endurance performance as the result of strength training in cross country skiers, which made them stronger, more powerful, and, especially, more economical. Paavolainen et al3 showed that endurance performance can be increased by adding explosive strength training (33% of training time) to classic endurance training. Balabinis et al4 concluded that concurrent training was more effective in terms of performance increase than strength and endurance training alone. Lastly, McCarthy et al5 and Marcinik et al6 showed that heavy resistance strength training led to lower lactataemia at a given intensity, because of a reduction in intrafibre pressure, partly explaining the improvement in submaximal endurance performance.

Concurrent training versus endurance or strength training
Absolute (l/min) and relative (ml/kg0.75/min) VO2MAX had improved considerably after the various training programmes (table 2). For absolute VO2MAX, the E+S, E, and S+E groups showed comparable adjusted average values, whereas relative VO2MAX had increased more in the E+S group than the other groups (fig 3). This shows that expressing VO2MAX appropriately is paramount as it may allow smaller changes to be observed. The improvements in the combined groups were slightly higher than those observed in previous studies using similar concurrent training.7 10 14 17 In contrast with our study, no changes in VO2MAX were observed in previous studies.2,5,9,11 These differences can be explained by the training programmes (form, intensity, frequency, and duration), the initial level, and the age and sex of the subjects. Other mechanisms may be involved, including particularly the conflict between the physiological adaptations, in addition to muscular hypertrophy which produces an increase in body mass.

Endurance and strength training sequencing
The most important finding of this study was that the intra-session order of strength and endurance training influences the training induced adaptations. The improvement in VO2MAX (ml/kg/min) was greater in the E+S group than in the S+E group (13.6% v 10.7%) (table 2). Previous studies have examined the effects of intra-session sequence order of strength and endurance training on aerobic adaptations. Collins and Snow17 showed that the training sequence did not have any effect on the change in VO2MAX. Gravelle and Blessing18 reported that concurrent training limited the increase in VO2MAX when endurance training preceded strength training compared with strength before endurance training (5.3% v 8.0%) in female students. It was argued that, when strength training was preceded by acute bouts of endurance and exhaustive dynamic resistance exercise, the subsequent strength training intensity was impaired, resulting in less strength improvement. The authors stressed the fact that it is still not known if the reverse was true. Our results may be partly explained by fatigue resulting from the strength training which may have influenced at least the physiological adaptations to endurance training, despite the fact that, from the training records, the endurance training intensity was not modified. Any possible effect of
Endurance training followed by strength training produced greater improvements in endurance performance and aerobic capacity than the reverse order or if the training methods were performed separately.

ACKNOWLEDGEMENTS

We thank Dr Zakia Bartagi, Dr Ali Ben Khedher, and Dr Mourad Hamblè for invaluable help.

What this study adds

Endurance training followed by strength training produced greater improvements in endurance performance and aerobic capacity than the reverse order or if the training methods were performed separately.
