ABSTRACT
Purpose The available scientific research regarding injury prevention practices in international football is sparse. The purpose of this study was to quantify current practice with regard to (1) injury prevention of top-level footballers competing in an international tournament, and (2) determine the main challenges and issues faced by practitioners in these national teams.

Methods A survey was administered to physicians of the 32 competing national teams at the FIFA 2014 World Cup. The survey included 4 sections regarding perceptions and practices concerning non-contact injuries: (1) risk factors, (2) screening tests and monitoring tools, (3) preventative strategies and (4) reflection on their experience at the World Cup.

Results Following responses from all teams (100%), the present study revealed the most important intrinsic (previous injury, accumulated fatigue, agonist:antagonist muscle imbalance) and extrinsic (reduced recovery time, training load prior to and during World Cup, congested fixtures) risk factors during the FIFA 2014 World Cup. The 5 most commonly used tests for risk factors were: flexibility, fitness, joint mobility, balance and strength; monitoring tools commonly used were: medical screen, minutes/matches played, subjective and objective wellness, heart rate and biochemical markers. The 5 most important preventative exercises were: flexibility, core, combined contractions, balance and eccentric.

Conclusions The present study showed that many of the National football (soccer) teams' injury prevention perceptions and practices follow a coherent approach. There remains, however, a lack of consistent research findings to support some of these perceptions and practices.

INTRODUCTION
Injury prevention in top-level football is of utmost importance given the negative outcomes borne out in reduced performance, financial impact and long-term health of players.8 To overcome the significant cost due to injuries as well as reduce the early onset of degenerative changes, sports medicine and science should ideally assist practitioners in the identification of important risk factors for injury occurrence and aid in the provision of evidence-based preventative recommendations. However, scientific investigations and information from the elite echelons of world football are sparse and much remains unknown in this domain.5 6

Two studies3 6 have started the process of quantifying the actual practices of top-level football organisations in order to provide recommendations on how to align injury risk factors with preventative practices in professional club settings. The first5 surveyed the perceptions and practices of premier league clubs worldwide and revealed the most important perceived risk factors (previous injury, fatigue, muscle imbalance), alongside the most commonly used screening tests (functional movement screen, questionnaires, isokinetic muscle testing) and preventative exercises (eccentric, specific hamstring eccentric focused, balance/proprioception) included in their injury prevention programmes. The second study6 systematically reviewed the scientific evidence underpinning these most important perceptions and practices. The authors showed that the majority of these perceptions and practices did not possess a strong level of scientific evidence or graded recommendation for use in the practical setting. Regardless, these studies represent football in the specific context of professional clubs where the training programmes, logistical demands and available facilities differ from those in competitions involving national teams, such as at the FIFA World Cup. While injury rates in the FIFA World Cups have significantly declined in each subsequent tournament since 1998,7 the time-loss match injury rates remain higher in comparison to those reported as per professional club standards (40.0/1000 h vs 26.7/1000 h, respectively).7 8 The differences in injury rates could be explained by several factors; accumulated fatigue as the World Cups are contested following a full competitive club season, changes in training style and the high level of player competitiveness at the most important tournament worldwide.

Therefore, the purpose of the present study was to quantify current practice with regard to (1) injury prevention of top-level footballers competing in the FIFA 2014 World Cup, and (2) determine the challenges faced by practitioners in implementing their injury prevention programmes.

METHODS
Participants
National team physicians of the 32 teams competing at the FIFA 2014 World Cup in Brazil were invited to participate in this structured survey. An invitation was emailed to the physicians of all 32 national team federations on 20 December 2014 introducing the concept and objectives of the survey, and provided a web link to access the survey.

Physicians were asked to submit their response online. If a question was unanswered, it was excluded from the analysis. Data were collected...
retrospectively between 20 December 2014 and 1 February 2015. All physicians ‘consented to participate’. The list of participating national teams is presented in table 1. When there was more than one physician in a team, both physicians were asked to complete one survey with collaborative input.

Survey
The survey was constructed in English, French and Spanish and administered via an online survey software (Survey Monkey, http://www.surveymonkey.net) and consisted of 27 questions (17 closed ended and 10 open ended; see online supplementary appendix A) with four sections: (1) perceived risk factors for non-contact injuries, (2) screening tests and monitoring tools used to identify non-contact injury risk, (3) non-contact injury prevention strategies used, perceived effectiveness and implementation strategies, and (4) reflection on the effectiveness of injury prevention strategies, challenges faced and future directions for research. The questions were designed by six experts—three sport scientists, two physicians and a sports medicine specialist. The design of questions took into consideration their combined knowledge and experience of sports medicine, and the science in professional and international football, in addition to their work in peer-reviewed research and implementing survey-based research. The survey was pilot tested with two national team physicians before the official invitations were sent. Following the pilot survey, four questions pertaining to ‘psychological strategies’ were added.

Survey analysis
The raw data was exported from Survey Monkey to Microsoft excel and analysed independently by the research team. To calculate the overall importance of risk factors, points were awarded based on a scale developed for previous survey research. Each time a physician rated a risk factor, it was awarded 3 points; ‘important’—2 points; ‘somewhat important’—1 point; ‘not sure’—0.5 points and ‘not important’—0 point. Points were then summed up and risk factors ranked in order of highest summed points to the lowest. A similar method was used to determine the ‘5 most important preventative exercises’. Physicians were asked to rank in order of importance (1st to 5th) the preventative exercises they considered the most important in their injury prevention programme. Points were awarded based on a scale developed for the previous survey research: exercises rated in first position were given 5 points, second—4 points, third—3 points, fourth—2 points; and fifth—1 point. Points for each exercise were summed and ranked in order, from highest to lowest. Regarding open-ended questions, individual responses were subjectively analysed for similarities and were grouped by the lead author (AM) into the appropriate overall category.

RESULTS
Survey
Background information
All (100%) physicians submitted survey responses. Thirty-two surveys based on the perceptions and practices of 37 physicians were included for analysis (5 teams with 2 physicians).

Perceived non-contact injury risk factors
As based on national team physicians’ perceived rating of importance, the five most important ‘intrinsic’ and ‘extrinsic’ risk factors for non-contact injury are presented in table 2.

Assessment and monitoring of injury risk
All 32 teams confirmed undertaking testing and monitoring of their players during both the pre-training camp and World Cup tournament. A total of 30 (94%) teams confirmed that they assessed and determined injury risk based on an ‘individual player risk profile’. The five most commonly used injury-screening tests and monitoring tools are presented in figures 1 and 2 (respectively).

Injury prevention strategies
Twenty-nine (91%) teams implemented an exercise-based injury prevention programme. Twenty-eight (97%) of these teams individualised the exercise programme according to players’ individual injury risk profile determined from testing conducted prior to their World Cup camp. Of the teams implementing an exercise prevention programme, 24 (83%) did so in both the

Intrinsic and extrinsic risk factors

Intrinsic risk factors for non-contact injuries include factors such as muscle imbalances, fatigue, and previous injury. Extrinsic risk factors include the environment, such as field conditions and equipment. These factors interact with athletes in various ways, and the way in which these factors interact with the athlete is crucial in understanding injury risk.

Non-contact injury risk factors

In non-contact injuries, the risk factors are related to the athlete’s intrinsic factors, such as muscle imbalances and fatigue, and extrinsic factors, such as the environment. The risk factors are often interrelated, and understanding their interaction is crucial in preventing injuries.

Efficacy of and challenges to preventative strategies

Twenty-six (81%) national teams stated that they perceived their injury prevention strategies to be ‘effective at reducing/limiting injuries, however, could have been better’, while five (16%) stated that they ‘could not have done better’ and one team was ‘not sure’. Thirty (94%) national teams responded to the question ‘What were the main challenges faced in preventing injuries?’ These responses are grouped into nine main categories and listed in table 4.

Compliance to injury assessment and prevention

Physicians’ perceived ‘importance’ of coach compliance to their injury prevention practices is detailed in table 3. Furthermore, figure 4 shows the level of coach compliance to the individualisation of players’ training programme and recommendations for injury prevention as rated by physicians.

imbalance are deemed of particular importance in the national team context. Currently, previous injury as a risk factor in top-level footballers has a strong level of scientific evidence, whereas fatigue has a low level of evidence and muscle imbalance findings are too inconclusive to assign any specific level of evidence. Nevertheless, the present findings suggest that future research on national teams should focus efforts on these aforementioned intrinsic risk factors.

**Extrinsic risk factors**

In line with the perceptions of the physicians in this survey, reduced recovery time (1st) and a congested match schedule (3rd) are supported risk factors for injury in top-level footballers. Three of the other perceived extrinsic risk factors, namely, training load prior to the World Cup (2nd), training load during the World Cup (joint 3rd place) and the number of matches played during the club season (joint 4th place) can be considered specific to national team concerns and are under the umbrella term of ‘workload’ imposed on the player (ie, physical and mental loads from training and matches). Previous research has shown that 60% of players who played in more than one match per week during the 10 weeks prior to the World Cup 2002 incurred injuries or underperformed during that World Cup. Although not currently shown in top-level footballers, workloads from training and matches have been associated with injury in other football codes. Investigations into the association between workload and injury in top-level football players are, therefore, highly pertinent.

**Assessment and monitoring of injury risk**

In sport, each athlete has a unique risk value and it is important to examine those intrinsic and extrinsic risk factors that interact to make an athlete susceptible to injury, ideally before the injury inciting event occurs. Ninety-four per cent of teams at the FIFA 2014 World Cup assessed their players’ individual injury risk profiles with the common tests and monitoring tools outlined below.

**The ‘5’ most commonly used injury risk screening tests**

The ‘5’ most commonly used screening tests used by national teams were flexibility (dynamic and static), physical fitness, joint mobility, balance/proprioception and evaluation of both muscle endurance and peak strength.

Tests of physical fitness, balance/proprioception and muscle strength are in line with their similarly ranked importance as risk factors outlined earlier. Accordingly, there appears to be a coherent approach of practitioners in terms of implementing screening tests that potentially identify what they consider to be among the most important intrinsic risk factors for their players. In contrast, as risk factors, joint mobility/function and flexibility were ranked as 11th (58/96 points) and 12th (56/96 points) out of 18 ranks, respectively. Despite this lower ranking and conflicting research about these as risk factors for professional footballers, 91% of physicians rated joint mobility/function and flexibility as having at least some importance. The fact that these tests are generally easy to implement may explain why these are among the most widely used by national teams.

**The ‘5’ most commonly used monitoring tools**

The ‘5’ most commonly used monitoring tools were daily medical screens, tracking of number of matches/minutes played, subjective and objective wellness, heart rate and biochemical markers (biochemical and objective wellness jointly share 5th rank). These monitoring tools are consistent with national team physicians’ perceptions of injury risk factors in that they can provide a range of outcome measures of how the player is ‘coping with the workload’, whether physically (medical screen, heart rate, biochemical and objective markers of physical state) or mentally (subjective scales). Interestingly, recovery of muscle force was monitored in only nine (28%) teams. This may be due to lack of valid, reliable and sensitive monitoring tools that are easy to implement and require little equipment in such logistically demanding settings.

**Exercise-based injury prevention strategies**

The key preventative exercises used by national teams were similar to those reported for premier league clubs, albeit in a slightly different order of importance. For example, core, balance/proprioception and eccentric exercise also feature in the ‘Top 5’ of national teams’ exercises. At the time of the present survey there is still no direct scientific evidence that core exercises can reduce injury risk in top-level footballers, although evidence from other top-level football codes suggest some preventative capacity. Similarly, there remains a lack of scientific evidence for balance/proprioception exercise with only a single study in top-level football suggesting reduced ankle injury occurrence. Despite some studies suggesting support for eccentric exercise, it too has a weak level of evidence in the scientific literature as it cannot be ascertained that the beneficial effects on injury are specifically from the eccentric component. Interestingly, in the present survey a ‘combination’ of...

Efficacy of and challenges to implementing injury prevention strategies

The majority (81%) of teams that suggested their overall pre-

Obtaining compliance from the coaching staff was viewed as one of the main challenges rated by physicians to prevent injuries. While 31% of teams reported perfect compliance from their coaches, there appears to remain room for improving compliance and in turn, further reducing/limiting non-contact injuries. Investigations into coach compliance is a relatively new area of research; however, it appears essential that future studies focus efforts on how to maximise coach integration into the injury prevention programme if such strategies are to be optimised. One suggestion has been to ‘capture the attention of coaches’ by transforming medical statistics into a meaningful context for the coaches; for example, give them specific instances of the negative effect of injury on team selection, performance and results. It would be interesting, therefore, to determine what ‘details’ are important to coaches and how these can be imple-

Further, nine specific categories pertaining to ‘challenges faced’ (table 4) in preventing injuries were highlighted in addition to the six areas where practitioners suggest further research (table 5) is necessary to provide meaningful solutions in the practical setting. One overwhelmingly consistent response pertained to the need for research on top-level players. This is qualitatively evidenced by one statement that suggested; “as long as clubs (top level) do not provide access to scientific studies, we will remain in this unsatisfactory status”, that is, where there is little information on preventing injuries at the top level.

A limitation to be recognised is the retrospective nature of the present survey (ie, physicians were surveyed 5 months after the World Cup), and it is acknowledged that such a study design could increase the risk of reporting bias. However, this is a sup-

CONCLUSION

In conclusion, the present study has highlighted the most importantly perceived intrinsic and extrinsic risk factors for non-contact injury in the highest level of international players competing at the FIFA 2014 World Cup. The most commonly used tests and monitoring tools have been identified in addition to the five most important exercises that were incorporated into the injury prevention programme. In a first, the perceived effect-

Future directions

Future research should concentrate on what is important to practitioners for identifying injury risk (eg, significant risk factors, valid and reliable tests) and the effects of preventative strategies. Also of importance is that future research should
investigate aspects related to maximising coach compliance. Practitioners operating at the top level are strongly encouraged to share knowledge, experiences and data (eg, player match and training loads, injury information, individual characteristics) with researchers. The present authors, therefore, respectfully suggest these respective challenges: one to the researchers and one to the practitioners in top-level football. To researchers—carefully consider the perceptions and practices that are important to practitioners (eg, as shown in this study) and focus future investigations to provide the appropriate solutions. To practitioners—form collaborative relationships with applied researchers and/or academic institutions to ensure that future research is directly applicable.

What are the new findings?

▸ We have revealed the most common perceptions and practices of physicians practicing at the FIFA 2014 World Cup regarding:
  - Risk factors for non-contact injuries
  - Screening tests and monitoring tools used to develop a players’ individual risk profile
  - Preventative strategies used
  - Challenges to implementation
  • We have also provided new information to guide researchers and practitioners to collaboratively contribute to the advancement of injury prevention in elite footballers.

How might it impact clinical practice in the near future?

▸ The information revealed in this survey may allow a more coherent approach for practitioners in:
  - Determining risk factors
  - Choosing appropriate tests and monitoring tools
  - Implementing prevention strategies
    □ Exercise based
    □ Psychology based
