ABSTRACT

Background Knowledge of injury patterns, an essential step towards injury prevention, is lacking in youth handball.

Aim To investigate if an increase in handball load is associated with increased shoulder injury rates compared with a minor increase or decrease, and if an association is influenced by scapular control, isometric shoulder strength or glenohumeral range of motion (ROM).

Methods 679 players (14–18 years) provided weekly reports on shoulder injury and handball load (training and competition hours) over 31 weeks using the SMS, phone and medical examination system. Handball load in a given week was categorised into (1) <20% increase or decrease (reference), (2) increase between 20% and 60% and (3) increase >60% relative to the weekly average amount of handball load the preceding 4 weeks. Assessment of shoulder isometric rotational and abduction strength, ROM and scapular control was performed at baseline and midseason.

Results An increase in handball load by >60% was associated with greater shoulder injury rate (HR 1.91; 95% CI 1.00 to 3.70, $p=0.05$) compared with the reference group. The effect of an increase in handball load between 20% and 60% was exacerbated among players with reduced external rotational strength (HR 4.0; 95% CI 1.1 to 15.2, $p=0.04$) or scapular dyskinesia (HR 4.8; 95% CI 1.3 to 18.3, $p=0.02$). Reduced external rotational strength exacerbated the effect of an increase above 60% (HR 4.2; 95% CI 1.4 to 12.8, $p=0.01$).

Conclusions A large increase in weekly handball load increases the shoulder injury rate in elite youth handball players; particularly, in the presence of reduced external rotational strength or scapular dyskinesia.

INTRODUCTION

Shoulder pain and problems represent a significant health burden in senior handball, with reported point prevalence proportions of shoulder pain between 19% and 36% at season start,^{1–3} and average weekly prevalence proportions of shoulder problems of 28% during the season.¹ Also, shoulder pain in senior players has been reported to have an impact on the athletes' performance, training activities^{1–3} and daily life.² Early identification and modification of risk factors in youth handball are thus warranted for primary prevention of the subsequent musculoskeletal disorders in adults. However, knowledge about the incidence and risk factors, the integral first step towards injury prevention,⁴ is lacking in this age group.

Traditionally, studies have investigated associations between non-participation-related risk factors,

such as glenohumeral range of motion (ROM),^{1 5–8} shoulder strength^{1 7 9 10} and scapular control,^{1 11–13} and risk of shoulder injuries among overhead athletes. However, sports injury research needs to move from simple analyses of risk factors and concentrate on how these factors interact among other determinants for injury.¹⁴ Injury occurrence results from a combination of possessing different risk factors and participating with these risk factors.¹⁵ On this premise, handball participation must be considered a primary risk factor for shoulder injury, while non-participation-related risk factors like strength, glenohumeral ROM and scapular control influence the amount of handball participation a player can tolerate before shoulder injury occurs.¹⁶

As a measure of participation, several studies have investigated the relationship between training load and injuries in a variety of sports other than handball, and there is growing evidence that a rapid increase in training load increases the risk of overall injury.^{17 18} However, no studies have investigated if the vulnerability to a rapid increase in competition and training load is influenced by non-participation-related risk factors.

The objectives of the present study of elite adolescent handball players were to investigate if increases in weekly handball load, defined as the cumulative volume of training and competition hours, are associated with increased shoulder injury rates compared with a minor increase or decrease, and if an association is influenced by scapular control, isometric shoulder strength and glenohumeral ROM. The following *a priori* defined hypotheses (H) were tested:

H1. Players who increase their handball load by more than 60% in 1 week, relative to the weekly average of the preceding 4 weeks of handball load, have an increased shoulder injury rate compared with those who increase or decrease below 20%.

H2. The association between a moderate increase in handball load (i.e., 20–60% load) and shoulder injury rate will be exacerbated in players with abnormal shoulder characteristics (scapular dyskinesia, reduced shoulder isometric strength and abnormal shoulder ROM). No exacerbation in the association between a high increase in weekly handball load (ie, increase above 60%) and shoulder injury rate will exist in players with abnormal shoulder characteristics.

METHODS

Study design

In the present cohort study, we followed elite youth handball players for a full competitive handball

To cite: Møller M, Nielsen RO, Attermann J, et al. *Br J Sports Med* 2017;**51**:231–237.

season over 31 weeks from 13 October 2013 to 11 May 2014. The players were recruited from August to October 2013. Players who were not enrolled at baseline were allowed to enter the study at midseason (1 January to 1 March 2014). Methodological data from this study have previously been reported (Personal communication, 2016. M Møller, N Wedderkopp, G Myklebust, *et al.* The SPEX sport injury surveillance system is a feasible and valid approach to measure exposures and injuries in elite youth sport). According to the Danish Act on Research Ethics Review of Health Research Projects, The Ethics Committee of Central Denmark Region deemed the study to be exempt from full ethical review (request 89/2013) due to the study design (observational study). Permission for the study was granted by the Danish Data Protection Agency (File 2013-41-2137).

Participants

Players were recruited from all Danish First Division U-18 (range 16–18 years of age) teams and First Division U-16 (range 14–16 years of age) teams from clubs as described previously (Personal communication, 2016. M Møller, *et al.*). All players irrespective of current or previous shoulder pain were eligible for participation in the study. However, players were excluded if they reported a history of (1) previous shoulder surgery, (2) previous glenohumeral dislocation, (3) glenoid labrum tear, (4) rotator cuff tear or (5) fracture in the shoulder region within the previous 6 months.

Outcome

The primary outcome of interest was any new shoulder injury in the dominant arm, defined as *any handball-related shoulder problem irrespective of the need for time loss or medical attention*. Injury status was monitored continuously during follow-up using the SMS, phone and medical examination sports injury surveillance (SPEX) system, which has been described in detail elsewhere (Personal communication, 2016. M Møller, *et al.*). Briefly, SPEX obtains weekly injury and handball participation information from players by SMS messaging and, in a case of injury, telephone interview, and physical examination by medical personnel within 1–2 weeks.

The outcome was based on the players' response to the following SMS question in SPEX: *Have you been able to participate in handball training and match WITHOUT any physical problems (pain, discomfort, soreness, stiffness) or medical attention or illness during the past week?* Injuries were classified as shoulder injury based on the follow-up telephone interview.

Primary exposure

The primary exposure of interest was the weekly change (increase or decrease) in handball playing load defined and calculated as the amount of hours of handball playing (training and match hours)¹⁸ derived from players' SMS answers in SPEX in the current week divided by the weekly average amount of playing hours during the preceding 4 weeks.¹⁹ For the analyses, we decided a priori to categorise the player's weekly reports of handball load into the following three primary exposure groups: (1) <20% increase or decrease, (2) between 20% and 60% increase or (3) >60% increase in handball load. The cut-off values were chosen based on the weekly mean handball playing hours (estimated to be ~5 hours/week) in injury-free weeks. Normally this is based on two to three handball-training activities and one match. An increase of 1 hour (20% increase) would be equal to one extra weekly activity, whereas an increase

of 60% would equal two or three extra weekly handball activities.

Also, 4-week average periods below 0.74 hours (equals a z-score of -2) were categorised into a fourth group so that a small increase in handball activities within a current week following a very low preceding 4-week average would be excluded from the three primary groups.²⁰ Furthermore, the first 4 weeks of participation in the study, in which it was impossible to calculate the previous 4 weeks' average, were included in the analyses as a fifth group.

Effect measure modifiers

Factors included in the statistical analyses as modifiers of the effect of handball load on shoulder injuries were the shoulder assessments for scapular control,²¹ isometric rotational and abduction strength and ROM. (Personal communication, 2016. M Møller, J Attermann, G Myklebust, *et al.* The reliability of field-based measures of shoulder function in elite youth athletes). All strength measures were adjusted for body weight.

We created cubic splines with 4 knots (using Stata's mkspline command; Stata 14, StataCorp LP, College Station, Texas, USA) to dichotomise the continuous shoulder ROM and strength assessments. Shoulder assessments were thus included in the analyses as presented in table 1.

At baseline, all players attended a shoulder assessment session in the players' club. We aimed to repeat all shoulder assessments for all accepting players during the midseason from 1 January to 1 March 2014.

Owing to poor reliability and agreement, the isometric strength measurement procedures were modified according to our previous results (Personal communication, 2016. M Møller, *et al.*). We recruited four physiotherapists to perform the shoulder assessments for each assessment parameter. The physiotherapists were blinded to the player's SMS injury and exposure reports. For each physiotherapist, we investigated the test-retest reliability on 19 male u-18 handball players (ROM, isometric strength). Inter-reliability for scapular dyskinesis were evaluated on 20 physiotherapy students. During the main study, the physiotherapist assessing ROM stopped after baseline measurements and was replaced with another, whose reliability previously has been established. The shoulder assessment procedures, reliability results and applied statistics are described in detail in online supplementary appendices 1 and 2.

Table 1 Cut-off values for effect measure modifiers included in the analyses

	Reference	Abnormal
Scapular control	Normal + Subtle	Obvious
Rotational strength		
ER:IR ratio dominant arm 0 rotation	>0.75	≤0.75
ER:IR ratio dominant arm 30 rotation	>0.75	≤0.75
Abduction strength		
Difference dom vs non-dom	>0.065 N/kg	≤0.065 N/kg
Glenohumeral range of motion		
TROM difference dom vs non-dom	>-10°	≤-10°
IR difference dom vs non-dom	>-7.5°	≤-7.5°
ER difference dom vs non-dom	>-10°	≤-10°
Dif IR dom vs non-dom:Dif ER dom vs non-dom	≤2.7	>2.7

Dif, difference; dom, dominant arm; ER, external rotation; IR, internal rotation; N, newton; non-dom, non-dominant arm.

Statistical analysis

Cox proportional hazards regression with frailty was used to estimate hazard ratios (HRs) using calendar weeks as time-scale.²² All observations, in which the players did not report any playing time, were excluded from the analyses. The primary exposure (change in handball load) was included in the analyses as a time-dependent exposure.²³ Using this approach allowed us to take the players' weekly change in handball load into account by enabling all players to transit between the three primary exposure groups by the end of each week during the 31-week follow-up using delayed entry. The categorisation of handball load and the corresponding transition between them was based solely on the player's responses to the SMS questions. Increase below 20% or decrease in handball load was chosen as the reference group because we hypothesised such players would have the lowest injury rate. Test for no difference between survival functions in the three primary exposure groups was used to examine if a difference across the three primary exposure groups existed. Similar to change in handball load, the shoulder assessments (effect measure modifiers) were included as time-dependent covariates, providing players with shoulder follow-up measurements the possibility to transit between strata after ~15 weeks. Players not tested at follow-up kept their baseline shoulder assessment throughout the study. Handball-specific injuries unrelated to dominant shoulder injuries were included as competing risks. Players were not censored in case of an injury but were censored in case of lack of motivation, or by the end of the 31-week follow-up, whichever came first. The assumption of proportional rates was evaluated by log-minus-log plots. Shoulder injury incidence rate was calculated as the number of new and recurrent injuries during the study divided by the sum of exposure hours expressed in 1000 hours of total exposure hours (match and training). Poisson regression was used to estimate the incidence rate as a function of follow-up time in weeks and to test if this varied over time points during the season. *p* Values were considered statistically significant at $p \leq 0.05$. Medicine students, blinded to the purpose of this study, performed the data entry. All statistical analyses were unblinded conducted in Stata V14.1 software (StataCorp, College Station, Texas, USA).

Figure 1 The weekly predicted incidence proportion of new shoulder injuries during a 31-week handball season in adolescent handball.

RESULTS

The details of the participant flow and the demographics of the study population have previously been reported (M Møller, *et al.* 2016. In review). The sample of 679 players (44% female), representing 52 teams (of these, 37 U-18), reported 709 new injuries classified by telephone interviews via the SPEx system. Of these, we classified 106 (14%) as shoulder injuries (85 in the dominant arm) incurred during 73 546 playing hours, which corresponds to an incidence rate of 1.4 (95% CI 1.2 to 1.7) per 1000 playing hours. There was a significant change in risk of new shoulder injury during the season ($p < 0.001$) (figure 1).

The risk factor analysis included 68 shoulder injuries sustained in the dominant arm (eight players and 17 injuries were excluded from the analysis after excluding observations with zero handball load the preceding week). Of the 68 injuries, six players sustained two injuries. Thirty-three out of 68 injuries (49%) were classified as traumatic. The number of players tested and included for each effect measure modification analysis are listed in figure 2.

Table 2 illustrates the number of weeks at risk by an increase in handball load groups according to baseline factors.

The crude analysis of the increase in handball exposure above 60% was associated with an increased shoulder injury rate compared with those increasing <20% (table 3).

Scapular dyskinesis and decreased external rotational strength in 30° rotation significantly modified the effect of handball load if players increased handball load between 20% and 60% (scapular dyskinesis and external rotational strength) or above 60% (external rotational strength). No significant differences across strata of shoulder ROM or abduction strength were found (table 4). We found no differences between the three primary exposure groups in any of the analyses (*p* values from 0.09 to 0.68).

DISCUSSION

The present study is the first large cohort study investigating the synergy between participation-related and non-participation-related risk factors for shoulder injuries in sports.

A noticeable effect size (HR=1.91) was observed in the crude analysis. The injury rate was greater among players who increased

Figure 2 Numbers of players tested and included in the effect measure modification analyses. their handball load by more than 60% compared with those players who decreased or increased their handball load below 20%. In addition, scapular dyskinesis and decreased external strength at 30° rotation exacerbated the effect among players increasing in handball load to a moderate extent (20–60%).

Our a priori hypotheses were supported by these findings. They indicate that a 60% increase in handball load can increase the shoulder injury rate even in players with normal shoulder characteristics. Also, scapular dyskinesis and reduced external rotational strength make players prone to shoulder injury at a

moderate increase in handball load, compared with players with normal scapular control and external rotational strength. Importantly, though, if players with scapular dyskinesis or reduced external rotation strength do not increase their handball load by more than 20%, they are not more predisposed to shoulder injury compared with players with normal characteristics. These findings suggest that large weekly increases in handball load are the primary risk factor for shoulder injuries in youth handball. However, reduced external rotational strength also accentuated the effect of handball load on shoulder injury rate at an increase in handball load above 60%, which may indicate that the cut point between a moderate and high increase in handball load should exceed 60%.

We found no significant differences across strata of shoulder abduction and ROM measurements. In fact, there were very small differences in ROM between dominant and non-dominant shoulders (results not shown), and it is likely that the normal soft tissue or/and bony adaptations to the repeated throwing reported in senior female handball² and from a variety of other sports^{8, 24–28} are not yet present in youth handball players.

In general, our results cannot be compared with those of other studies investigating non-participation-related risk factors, as to the best of our knowledge no other studies in overhead sport have examined the synergy between training and competition load and non-participation-related risk factors, but instead compare the crude association between non-participation-related risk factors and the subsequent risk of injury, or do not take sport participation into account.^{1, 5–13, 29}

The reported shoulder injury rate of 1.4 per 1000 playing hours was 2.5 times higher (incidence rate ratio 2.5, 95% CI 1.6 to 4.0) than the reported shoulder injury rate of 0.6 per 1000 playing hours previously reported in a similar population using a time-loss definition as injury outcome.³⁰

Methodological considerations

The present study's major strength is the applied statistical analysis that takes the dynamic changing nature of risk factors into account.¹⁵ However, our analyses are limited by the number of events that are required to perform these analyses. The effect modifier analyses were further limited by the fact that not all players were tested, which reduced the number of included injuries.

Information problems

Recall bias is limited for injury and handball load reports owing to the high weekly response rates (88–97%) to the SMS part in

SPEX and the 95% follow-up rates by telephone classification. Still, the comparisons between injury outcomes from SPEX and on-field and medical observers demonstrated that 10% of all injury registrations were missed by the SPEX sports injury surveillance system, indicating a risk of misclassification. Furthermore, although most players responded rapidly to the SMS messages, it is evident that some players reported their injuries with a delay of 1 week or more (Personal communication, 2016. M Møller, N Wedderkopp, G Myklebust, *et al.* The SPEX sport injury surveillance system is a feasible and valid approach to measure exposures and injuries in elite youth sport). This is particularly relevant in the applied analyses where the change in handball load the week before an injury was investigated. However, we find it plausible to assume that the potential misclassification of injury status is similar across handball load groups. If this is the case, such non-differential misclassification may lead to bias towards null (no difference in shoulder injury rate between handball load groups). Hence, the association between change in handball load and shoulder injuries is underestimated.

As regards the registration of handball load, we believe that the use of the SPEX sports injury surveillance system ensures more accurate results than would have been obtained in studies analysing handball exposure at a group level using observational methods. Still, there is a risk that some players have been misclassified into wrong weekly exposure groups during the season. However, the players were unaware of the purpose of the analyses. Consequently, they likely have not been motivated to either under-report or over-report their shoulder injuries. Any potential misclassification must thus be non-differential leading to an underestimation of the association between change in handball load and shoulder injuries.

The fact that the same physiotherapists, except for ROM, assessed the players' shoulder profiles twice during the study in order to accommodate the changing injury risk profile throughout the season was a key strength of the present study. The cut points in which the continuous strength and ROM measurements could be translated into dichotomous risk factors were defined in this study. These cut-off values would determine if a player was at increased risk of injury or not. It should be noted that there is a high risk of categorising players into wrong exposure group due to random measurement error, even though, we found no systematic bias and less wide limits of agreement for the newly developed strength and ROM assessments than previously reported (see online supplementary appendix 2). The physiotherapists were blinded to previously reported injuries before the follow-up, and also to the selected cut points. This limits the risk that the physiotherapists unintentionally have influenced the measurements in a particular direction. Therefore, the potential misclassification of the shoulder assessments may have been non-differential leading to an underestimation between the sports participation, the given effect modifier and the shoulder injury.

The above-mentioned potential misclassifications might have prevented us from detecting other associations between handball load and shoulder injury (type 2 error).

Selection problems

U-16 teams were invited to participate in this study only if their U-18 team accepted to take part in this research. Consequently, there is a possibility that the U-16 players included in this study were from more elite clubs, and their handball load habits might not reflect those u-16 players at less elite clubs. Less elite clubs may also have limited recourses, lack of access to medical

The total number of injuries was 68 and the total number of weeks at risk was 14 684.

*See the text for definition of progression.

†Denotes that the shoulder test (scapula control and isometric rotational strength at 30° rotation) significantly modifies the effect of workload ratio on handball-specific shoulder injuries.

–2 SD, weeks in which the 4-week average handball load was below –2 SDs from the mean; 4 weeks, the first 4 weeks of study, increase in handball load calculations not possible; Abd str., isometric abduction strength difference between dominant and non-dominant arm; ER ROM, external range of motion difference between dominant and non-dominant arm; I:E ROM, The ratio of the difference between internal rotation dominant arm vs. internal rotation non-dominant arm and difference external rotation dominant arm vs. external rotation non-dominant arm; IR ROM, internal range of motion difference between dominant and non-dominant arm; Rot str. 0, external:internal ratio rotational strength at 0° rotation; Rot str. 30, external:internal ratio rotational strength at 30° rotation; SI, shoulder injury; TROM, total range of motion difference between dominant and non-dominant arm; W, weeks.

and support staff. Therefore, these players may sustain more injuries than the u-16 players linked with an elite club participating in this study. This potentially skewed 'healthy player' selection might have led to selection bias in this age group.

We found no significant differences in hazards for injuries between players who attended the shoulder assessments and players who did not, limiting the risk of skewed selection, and thus selection bias.

Confounding

There is a high risk of known and unknown confounding due to the inherent nature of the prospective study design. The potential confounders were, a priori, assumed to be playing position and previous injuries. However, due to the low frequency of shoulder injuries reported in the present study, it was not possible to control for these factors within the analyses, and this is a limitation of this study.

CONCLUSION

Our findings demonstrated that the shoulder injury rate in elite youth handball players was nearly twice as high in the week following a 60% or greater increase in handball load when compared with a decrease or a small-to-moderate increase in handball load <20%.

In addition, the findings showed that an effect of a moderate increase between 20% and 60% in handball load was exacerbated by the presence of reduced external rotational strength or scapular dyskinesis and that reduced shoulder external rotational strength also exacerbated the effect of large increases in handball load above 60%. Finally, we found 2.5 times higher shoulder injury incidence rate among 14–18-year-old handball players than previously reported.

What are the findings?

- Large increase in weekly handball load is associated with an increased rate of shoulder injuries in youth handball.
- Scapular dyskinesis and reduced external rotational strength reduce the amount of increase in handball load a player can tolerate before injury occurs.
- Shoulder injury incidence in youth handball is more than twice as high as previously reported.

How might it impact on clinical practice in the future?

Coaches and support personnel should monitor youth handball players' handball load on an individual basis. Concerted efforts should be made to avoid rapid increases in handball load. Particularly for players with scapular dyskinesis and reduced strength, because players with these certain characteristics may be more vulnerable to shoulder injury already at a moderate increase in handball load.
