Does sex affect second ACL injury risk? A systematic review with meta-analysis

Akash D Patel,1 Garrett S Bullock,2 Jordan Wrigley,3 Mark V Paterno,4,5 Timothy C Sell,6 Justin M Losciale7,8

ABSTRACT

Objective To determine sex-based differences in risk of a second ACL injury (overall and by laterality) following primary ACL reconstruction in athletes who are attempting to return to sport.

Design Systematic review with meta-analysis.

Data sources Systematic search of five databases conducted in August 2019.

Eligibility criteria for selecting studies Studies reporting sex-based differences in the incidence of second ACL injury in athletes attempting to return-to-sports and who were followed for at least 1 year following primary ACL reconstruction.

Results Nineteen studies were included in this review, with seven studies excluded from the primary meta-analysis due to high risk of bias. The remaining 12 studies (n=1431 females, n=1513 males) underwent meta-analysis, with all 19 studies included in a sensitivity analysis. Total second ACL injury risk was 21.9% (females: 22.8%, males: 20.3%). Females were found to have 10.7% risk of an ipsilateral ACL injury and 11.8% risk of a contralateral ACL injury. Males were found to have 12.0% risk of an ipsilateral ACL injury and 8.7% risk of a contralateral ACL injury. No statistically significant differences were observed for total second ACL injury risk (risk difference=−0.6%, 95% CI −4.9 to 3.7, p=0.783, I²=41%) or contralateral ACL injury risk (risk difference=1.9%, 95% CI −0.5% to 4.4%, p=0.113, I²=15%) between sexes. Females were found to have a 3.4% absolute risk reduction in subsequent ipsilateral ACL injury risk compared with males (risk difference=−3.4%, 95% CI −6.7% to −0.02%, p=0.037, I²=35%).

Conclusion Both sexes have >20% increased risk of experiencing a second ACL injury. Any difference in the absolute risk of either a subsequent ipsilateral or contralateral ACL injury between sexes appears to be small.

Registration PROSPERO (CRD42020148369)

INTRODUCTION

Female athletes are at two to four times greater risk of primary ACL injury compared with males, even when controlling for sport and competition level.1-5 This difference has been attributed to anatomy, hormonal effects, neuromuscular control, biomechanics and sport participation.6-19 Understanding the underlying risk factors and differences between sex has led to successful development of primary prevention programmes that have shown the ability to reduce the risk of sustaining an ACL injury by half in all athletes, with a decrease of non-contact ACL injuries in females by two-thirds.20 These programmes are pivotal to the long-term health of athletes in reducing the risk of the initial ACL injury and in mitigating the risk of future complications associated with the injury, such as obesity, physical inactivity and osteoarthritis.21-23 Unfortunately, not all athletes will be protected from a primary ACL injury, often requiring ACL reconstruction as part of the treatment plan. Following surgical reconstruction and rehabilitation, athletes expect to return to sport at their prior level.24 Although returning to sport enhances the quality of life in athletes,25 it does expose them to the possibility of a second ACL injury,26,27 with 21%–23% of athletes experiencing either a re-tear of the ipsilateral graft or a new ACL injury to the contralateral knee.28-30 Age has been reported to be a risk factor for second ACL injury,31-34 with athletes younger than 25 years old experiencing a combined second ACL injury risk of 23%.28 Risk factors for second ACL injury also include allograft usage and lower self-reported confidence or psychological readiness.31 33 36 However, the relationship between sex and second ACL injury risk is less clear. One study reports that female athletes have a greater second ACL injury risk in both knees compared with males.29 Another study suggests that differences in risk of a second ACL injury are significantly higher in females when comparing contralateral ACL injuries (female=23.7%; male=10.5%), but no differences in ipsilateral ACL re-tear risk (female=8.5%; male=10.5%).30 Other studies have found no sex differences.37 38

Understanding risk factors regarding second ACL injury is vital to the health and well-being of athletes. When compared with primary ACL injury and reconstruction, second ACL injury and reconstruction are associated with an increased likelihood of meniscal damage, reduced thigh muscle explosiveness and strength, increased pain, higher risk of post-traumatic knee osteoarthritis and future physical inactivity.39-41 Similar to primary ACL injury, reducing the risk of second ACL injuries requires understanding if sex is a risk factor. The lack of consensus on which sex is most at risk for a second ACL injury may inhibit the rigorous development of effective second ACL injury screening and prevention programmes.

The purpose of this systematic review was to (1) determine the second ACL injury risk for patients included in studies followed for at least 12 months following their primary ACL reconstruction, (2) investigate the sex-based differences in risk of a second ACL injury following primary ACL reconstruction in active individuals attempting to...
return-to-sport, (3) determine the risk between sex and localisation of the second ACL injury (ipsilateral graft tear vs native contralateral ACL injury), and (4) determine if cohort age, percentage of cohort who return-to-sport, and pre-injury activity levels are moderators of the differences observed between male and female second ACL injury risk. We hypothesise that female athletes will demonstrate a higher second ACL injury risk compared with males, that female athletes will have a higher risk of contralateral ACL injuries compared with males and that younger age (<18 years) will modify sex-based differences in second ACL injury risk.

METHODS

Protocol, registration and critical appraisal

This systematic review and meta-analysis followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. The web-based platform for systematic review production, Covidence (Veritas Health Innovation), was used to manage all stages of the review process. AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews, version 2) was used to critically appraise this review.

Literature search

A medical research librarian (JW) conducted a computerised literature search using a combination of keywords and database-specific controlled terminology related to ‘ACL injuries’, ‘ACL surgeries’ and ‘re-injury’ in the following databases: MEDLINE via PubMed, Embase (Elsevier), CINAHL (EBSCO), SPORTDiscus (EBSCO) and Scopus (Elsevier). The search was conducted on 22 August 2019 and was not limited by date. Editors and comments were removed as were animal-only studies. Results from all databases (n=3932) were uploaded to Covidence for screening. Following completion of full-text screening, a manual search of citation lists from included studies was performed to identify relevant citations that were missed, and a query of prominent journals related to sports medicine and orthopaedics was performed to capture citations published following the completion of the systematic search. A detailed search strategy can be found in online supplemental appendix 1.

Inclusion and exclusion criteria

Articles were included in this systematic review if they met the following criteria: (1) study cohort’s average age was between 10 and 50 years; (2) undergoing any graft type ACL reconstruction; (3) attempting to return to sport, with a pre-injury or post-injury Tegner activity level of ≥7; (4) study reported second ACL injury incidence (ipsilateral graft rupture, native contralateral ACL injury or both); (5) ACL injuries were stratified by sex (or data were made available by authors); (6) study follow-up was at least 1 year following ACL reconstruction. Due to many studies not reporting activity levels using the Tegner scale, we used available information to determine equivalent activity levels appropriate for our cut-off including Marx activity score ≥8, International Knee Documentation Committee (IKDC) Level 1 or 2 sport determination, or descriptive information indicating Tegner ≥7. In addition, to ensure the majority of study participants were attempting to return-to-sport, we established that 55% of the entire sample must return-to-sport for the study to be included. This threshold was chosen based on previous work demonstrating 55% of athletes return to a competitive sport.

Articles were excluded if (1) study participants had a prior knee surgery to either knee or bilateral ACL reconstruction; (2) underwent non-surgical management for their ACL injury; (3) underwent a revision ACL reconstruction at the start of the study; (4) had a grade 3 PCL, MCL or LCL injury; (5) not written in English; and (6) studies were systematic reviews, narrative reviews, meta-analysis, editorials, letters to the editor or clinical commentaries. When two or more different studies used the same named cohort of participants, the study with the larger overall sample size was included in this review.

Study selection

Two reviewers (ADP, JML) independently screened all relevant titles and abstracts retrieved from the database search against the selection criteria. Full-text manuscripts of remaining eligible studies were evaluated with the same selection criteria. Any discrepancies between the two reviewers were resolved by a third reviewer (GSB). If further data clarification was necessary to establish study eligibility, contact with the corresponding and/or senior listed author(s) was attempted via email with a 2-week follow-up email if no initial response.

Assessment of risk of bias and strength of the evidence

Two reviewers (ADP, JML) independently assessed risk of bias for each study. Any discrepancies were solved through discussion and consensus. A post hoc change was made to the study protocol to follow current systematic review best practice guidelines for assessing risk of bias using domain-based, study design-specific tools versus study methodological quality.

We assessed risk of bias using three domain-based tools including the Cochrane Risk of Bias 2 tool for randomised controlled trials, the Risk of Bias Assessment tool for Non-Randomized Studies for observational studies including cohort, case-control and before-after studies, and the Cochrane Risk Of Bias In Non-randomized Studies – of Interventions tool for studies assessing the effect of interventions between groups.

We assessed each tool for the primary outcome of second ACL injury only as this was most pertinent to this review. For the Risk of Bias 2 tool, risk of bias judgement per study is noted as ‘low risk’ when all domains are judged to be at ‘low’ risk of bias, ‘some concerns’ of bias when one or more domains are judged to be at ‘some concerns’, or ‘high risk’ of bias when at least one domain is judged to be at ‘high’ risk of bias or when multiple domains have ‘some concerns’ of bias. For the Risk of Bias Assessment tool for Non-Randomized Studies tool, risk of bias judgement per study is noted as ‘high’ risk if ≥2 domains were rated as ‘high’ risk, ≥2 ‘unclear’ risk, or 1 ‘unclear’ and 1 ‘high’ risk. For the Risk Of Bias In Non-randomized Studies – of Interventions tool, risk of bias judgement per study is noted as ‘low risk’ when all domains are judged as ‘low’ risk of bias, ‘moderate’ risk when one domain is judged as ‘moderate’ risk of bias, ‘serious’ risk when one domain is judged as ‘serious’ risk of bias, or ‘critical’ risk of bias when one domain is judged as ‘critical’ risk of bias.

Strength of the evidence included in this review was judged using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) scale, which determines the overall certainty of the evidence per outcome that is statistically pooled and compared between groups. The GRADE scale assesses five factors concerning risk of bias (see tool descriptions mentioned previously), imprecision (width of CIs) and publication bias (determined by funnel plot). These factors lead to a reported score of high, moderate, low or very low quality of the evidence. The GRADE scale was applied to assess the evidence regarding sex-based difference in total, ipsilateral and contralateral second ACL injury risk. The lead author (ADP)
aggregated the necessary information for each GRADE domain and was reviewed by a second reviewer (JML) for accuracy and completeness. Any disagreements were settled through discussion and consensus.

Data extraction and primary outcome variables
Two reviewers (ADR, JML) independently extracted data from included studies using identical templates. Any discrepancies were solved through discussion and consensus. If further clarification on the reported data within included studies was necessary, contact with the listed corresponding authors was attempted. Study descriptive information including title, primary author, date of publication was recorded, as well as demographic information including sample size, participant age, participant sex, ACL reconstruction characteristics, pre-injury activity level, post-injury activity level, return-to-sport percentage and the diagnostic criteria used to determine a second ACL injury. To capture all possible second ACL injuries, diagnostic criteria used to determine a second ACL injury were not standardised in this review and determined via the methods used by each included study.

The primary outcome variables extracted were overall study incidence of a second ACL injury (graft rupture and native contralateral ACL injury), the incidence of a second ACL injury based on sex (male or female), incidence of second ACL injury (graft rupture and native ACL injury), the incidence of a second ACL injury (contralateral or ipsilateral), and the incidence of a second ACL injury based on the interaction of sex and laterality of injury (contralateral or ipsilateral).

**Statistical analyses**
Per current meta-analyses best practice recommendations, all studies assessed to be at high risk of bias were excluded from the primary meta-analyses to reduce compounding of bias, but were included in our sensitivity analysis (described later). Aggregated random effects incidence proportions with 95% CI were calculated for overall, ipsilateral and contralateral second ACL injuries for the total cohort and per sex. This calculation provides the cumulative incidence (expressed as a percentage) which is equivalent to the risk of experiencing a second ACL injury. Heterogeneity bias was assessed through Begg-Mazumdar and Egger’s calculations, with I² value reported (high heterogeneity: I² ≥50%, and p value <0.10).

To determine the relative and absolute risk of sustaining a second ACL injury between sexes, an inverse-weighted, DerSimonian and Laird random-effects risk ratio (RR) and risk difference meta-analysis were performed for overall, ipsilateral and contralateral second ACL injuries per sex at 95% CI. Both relative (RR) and absolute (risk difference) were reported to give a clear picture of the clinical relevance of the pooled estimates.

Pooled RR and risk difference statistics are reported with males as the reference population; thus, the calculations were RR = (female cumulative incidence/male cumulative incidence), risk difference = (female cumulative incidence–male cumulative incidence). Heterogeneity bias was assessed through Cochranes’s Q and I², with high heterogeneity determined with an I² ≥50% and a p value <0.10. Publication bias was assessed through funnel plots. Meta-regressions were then performed to determine the influence of age, pre-injury activity level and study return-to-sport percentage on overall, ipsilateral and contralateral second ACL injuries per sex. The variance explained through these confounders was assessed through R².

Sensitivity analyses were then performed to further understand the robustness of our results and the directions of biases. To determine if return-to-sport percentage introduced bias into our study, sensitivity analyses included studies that reported ≥85% return-to-sport. Further, to understand the direction and effect of bias in this literature, we performed a sensitivity analysis that included all studies, regardless of bias assessment (high risk of bias studies (n = 7) included). Incidence proportion analyses were performed in StatsDirect (StatsDirect, Merseyside, UK) and all RR and risk difference meta-analyses and meta-regressions were performed in R V.5.042 (R Core Team (2013). R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. URL http://www.R-project.org/) using the meta package.

**RESULTS**

**Search results**
The initial search resulted in 3932 potentially eligible studies, with one additional article discovered during the manual search that met our inclusion criteria (figure 1). After removal of duplicates, 1916 studies remained. Screening of title and abstracts yielded 300 studies for full-text analysis. Overall, 281 full-text articles were excluded for a variety of reasons as indicated in

**Figure 1** PRISMA flow diagram.
The remaining 12 were determined to be at low (n=11, 57.9%) risk of bias.

Seven studies (36.8%) were found to be at high risk of bias.53–59

The GRADE scale determined that the quality of evidence for the risk of sustaining a second ACL injury and ipsilateral ACL injury is ‘very low quality’, due to imprecision of the pooled RR and risk difference estimates and high levels of heterogeneity (online supplemental appendix 3). The quality of evidence for the risk of a contralateral ACL injury is ‘low quality’ because non-randomised studies were included (online supplemental appendix 3). This review met 15 of 16 reporting and quality criteria (94%) according to the AMSTAR-2 criteria (online supplemental appendix 4).

Study characteristics and demographics
Study demographic information, sample size, ACL reconstruction characteristics, activity levels, return-to-sport percentage and definition of a second ACL injury from all 19 included studies are available in table 2. From the 19 included studies, there were 4027 total participants (females=1715 (42.6%), males=2312 (57.4%))30 38 60–69 (online supplemental appendix 5). Seven studies were excluded from our primary analysis due to high risk of bias.53–59 Thus, 12 studies with 2944 participants (females=1431 (48.6%), males=1513 (51.4%)) were included in the primary meta-analyses.

Second ACL injury risk
Primary meta-analysis estimated the pooled risk of a second ACL injury for the total cohort and by sex, which are presented in figure 2A–C. The pooled risk of a second ACL injury (either graft tear or contralateral ACL injury) for both males and females was 21.9% (95% CI 16.7% to 27.6%, I²=92%).30 38 60–69 Females were found to be at 22.8% (95% CI 16.6% to 29.6%, I²=88%) risk for a second ACL injury. Males were found to be at 20.3% (95% CI 13.6% to 27.8%, I²=91%) risk for a second ACL injury.

Pooled risk of an ipsilateral ACL injury (for the total cohort and by sex) and contralateral ACL injury (for the total cohort and by sex) are presented in figure 3A–C (ipsilateral) and figure 4A–C (contralateral).

Of all male second ACL injuries, ipsilateral injuries accounted for 62.5% (95% CI 52.4% to 72.1%, I²=64%) of those injuries, with contralateral injuries accounting for 37.5% (95% CI 27.9% to 47.6%, I²=64%) of all male injuries (figure 5A,B). Of all female second ACL injuries, contralateral injuries account for 53.7% (95% CI 41.9% to 65.4%, I²=74%) of those injuries, while ipsilateral injuries accounted for 46.3% (95% CI 34.6% to 58.1%, I²=74%) of all female injuries (figure 6A,B).

Relative and absolute differences in second ACL injury risk by sex
Primary meta-analysis revealed there were no statistically significant differences between sexes in the relative risk of second ACL injury (RR=0.95, 95%CI 0.75 to 1.19, p=0.629, I²=50%) (figure 7A) or in the absolute risk of second ACL injury (risk difference=−0.6%, 95%CI −4.9 to 3.7, p=0.783, I²=41%). There was no statistically significant difference between sexes in ipsilateral ACL injury relative risk (RR=0.74, 95%CI 0.52 to 1.05, p=0.094, I²=52%) (figure 7B). However, females were

Review

found to have 3.4% reduced absolute risk of an ipsilateral ACL injury compared with males (risk difference = −3.4%, 95% CI −6.7% to −0.02%, p = 0.037, I² = 35%). Females were found to have 1.27 times higher relative risk (95% CI 1.00 to 1.61, p = 0.049, I² = 0%) of experiencing a contralateral ACL injury compared with males (figure 7C). Females were found to have a non-statistically significant, 1.9% increase in the absolute risk of experiencing a contralateral ACL injury compared with males (95% CI −0.5% to 4.4%, p = 0.113, I² = 15%).

Funnel plot assessment did not indicate concern for publication bias (online supplemental appendix 6). Meta-regression performed using participant age, pre-injury activity level and study return-to-sport percentage as moderators of second ACL injury, ipsilateral ACL injury and contralateral ACL injury risk revealed these factors did not impact the pooled risk values (R² = 0.0% for all three analyses).

Sensitivity analysis

Sensitivity analysis performed including studies with a sample return-to-sport percentage ≥85% (n = 6) showed no statistically significant differences in the relative risk of sustaining a second ACL injury between sexes (RR = 0.86, 95% CI 0.66 to 1.12, p = 0.273) or a native contralateral ACL injury (RR = 1.26, 95% CI 1.07 to 1.46, p = 0.011, I² = 0%). However, females were found to be at a 41% reduced relative risk (RR = 0.59, 95% CI 0.42 to 0.85, p = 0.004) of an ipsilateral injury compared with males in studies with high return-to-sport percentage (≥85%).

High risk of bias studies were added back into the primary meta-analysis (n = 7)33–39 to determine the effect and direction of observed bias in the available literature. This sensitivity analysis found no statistically significant difference between sexes in the overall relative risk of sustaining a second ACL injury (RR = 0.98, 95% CI 0.81 to 1.18, p = 0.799, I² = 32%). However, females were found to be at 29% reduced relative risk of an ipsilateral ACL injury (RR = 0.71, 95% CI 0.58 to 0.87, p = 0.0008, I² = 0%) compared with males, and females were found to have 1.35 times greater relative risk of experiencing a native contralateral ACL injury compared with males (RR = 1.35, 95% CI 1.07 to 1.70, p = 0.011, I² = 0%).

DISCUSSION

Currently, there is ambiguity regarding the relationship between sex and second ACL injury risk following primary ACL reconstruction. The results of this systematic review and primary meta-analysis determined that there is a negligible, non-statistically significant difference in the relative and absolute risk of experiencing a second ACL injury (both ipsilateral and contralateral combined) between sexes. Females may experience a small, 3.4% reduced absolute risk of a subsequent ipsilateral ACL injury compared with males. This review also found that females may

Figure 2  (A) Total cohort second ACL injury risk. Forest plot for the incidence proportion (risk) and 95% CI of experiencing a second ACL injury (ipsilateral and contralateral) in both male and female athletes combined. (B) Male second ACL injury risk forest plot for the incidence proportion (risk) and 95% CI of experiencing a second ACL injury (ipsilateral and contralateral) in male athletes. Figure 3  (A) Total cohort ipsilateral second ACL injury risk. Forest plot for the incidence proportion (risk) and 95% CI of experiencing an ipsilateral ACL injury in both male and female athletes combined. (B) Male ipsilateral second ACL injury risk. Forest plot for the incidence proportion (risk) and 95% CI of experiencing an ipsilateral ACL injury in male athletes. Dekker et al.63 was excluded from this analysis because data were not provided to quantify the number of male ipsilateral injuries. (C) Female ipsilateral second ACL injury risk. Forest plot for the incidence proportion (risk) and 95% CI of experiencing an ipsilateral ACL injury in female athletes. Dekker et al.63 was excluded from this analysis because data were not provided to quantify the number of female ipsilateral injuries.
experience 1.27 times higher relative risk of a subsequent contralateral ACL injury compared with males (95% CI 1.00 to 1.61, \(p=0.049\)). However, females were found to have only a small, non-statistically significant, absolute increase in subsequent contralateral ACL injury risk compared with males (risk difference = 1.9%, 95% CI −0.5% to 4.4%, \(p=0.113\)). This suggests that any difference in subsequent contralateral ACL injury risk between sexes is minimal at best.

### Risk of a second ACL injury

Males and females were found to be equally likely to experience a second ACL injury. Although a previous meta-analysis reported that females have higher odds of experiencing a second ACL injury than males,\textsuperscript{70} this discrepancy is likely due to the absence of considering return-to-sport percentage in their inclusion criteria. This suggests that their findings might better reflect general populace ACL injury trends. Having considered return-to-sport percentage, the present review reflects active individuals attempting to return to their prior level of activity and exposing themselves to higher levels of ACL re-injury risk.

Although females have been considered to be at increased risk of a contralateral ACL injury compared with an ipsilateral ACL injury,\textsuperscript{80} we found that females experience similar risk of sustaining an ipsilateral (11%) and contralateral (12%) ACL injury (figures 3C and 4C). However, differences between ipsilateral and contralateral ACL injury trends may occur at different rates.\textsuperscript{4} When factoring in time from return-to-sport to injury, females demonstrate a considerably increased rate of a contralateral ACL injury compared with an ipsilateral ACL injury.\textsuperscript{80} Our review did not factor in the rate of second ACL injuries because our focus was on determining the risk of second ACL injuries between sexes.

The primary analysis found that females demonstrated a small, 3.5% reduced absolute risk of experiencing an ipsilateral ACL injury compared with males. However, due to the number of statistical tests performed, this could be the result of type 1 error. Further, additive and multiplicative risks are not completely equal in analysis,\textsuperscript{71} with additive risk potentially providing improved multivariable risk assessment for multiple exposures, time to event hazards, and overall public health impact.\textsuperscript{71, 72}
While this review estimates there may be only negligible to small (and some not statistically significant) pooled sex-based differences in second ACL injury risk by injury laterality (ipsilateral vs contralateral), it is critical to note that both groups are still at >20% risk for either an ipsilateral or contralateral second ACL injury. Since both limbs remain at risk for a future ACL injury, this provides further evidence that suggests the contralateral limb may not be the most useful comparator when making rehabilitation and return to sport decisions.36 73–76 There needs to be continued efforts towards optimising rehabilitation,77 and standardising return-to-sport criteria and comparison metrics that limit reliance on the also-at-risk contralateral limb.75

The primary analysis also found that males appear to experience a larger proportion of ipsilateral second ACL injuries (62.5%) compared with contralateral ACL injuries (37.5%). These findings may be explained by the already present differences in baseline primary ACL injury risk between sexes (one in 29 females sustains a primary ACL injury compared with one in 50 males).4 One theoretical explanation for this second ACL injury trend is that both sexes may retain their baseline primary ACL injury risk following ACL reconstruction such that both limbs remain at elevated risk for an ACL injury in females, while males might have increased risk factors in the reconstructed (ie, ipsilateral) ACL, increasing injury risk compared with the uninjured (ie, contralateral) ACL. Because males are at much lower baseline risk of injury compared with females,4 surgical reconstruction and subsequent reduction in strength and function (ie, knee joint loading, movement patterns, psychological aspects of recovery) of that limb may be the strongest factors affecting ipsilateral graft injuries in males.78 79 This trend and its explanation require further research to understand the mechanism that underlies the higher proportion of male ipsilateral ACL injuries versus contralateral ACL injuries.

Age did not explain any variance within these findings. This may be due to the strict inclusion criteria used in the current study. The included studies demonstrated a homogenous age range and did not capture a substantial proportion of younger individuals (<18 years). Only 4 of the 12 studies in the primary meta-analysis had populations <18 years old, while 5 of the 7 studies excluded due to high risk of bias had populations <18 years old. Females have been shown in population-based studies to have a peak incidence of ACL injuries,80 81 and higher risk of a second ACL injury when they are <19 years old.29 30 36 Males appear to experience peak incidence of primary ACL injury in their mid-20s.80 81 A recent meta-analysis assessing second ACL injury differences between sexes following paediatric ACL reconstruction found that females experienced more contralateral injuries compared with males, but they did not calculate a meaningful measure of association that informs the magnitude and direction of the relationship.82 Further methodological concerns include inappropriate statistical pooling and comparisons which indicate these results should be interpreted with caution. Recent evidence has challenged the notion of age as a risk factor for second ACL injury and concluded that functional readiness and returning to level 1 sport are the key factors associated with second ACL injury risk,83 leading to continued ambiguity regarding the interaction between age and sex on second ACL injury risk.

Risk of bias

This review identified seven studies (36.8%) considered to be at high risk of bias and were removed from our primary analyses to not compound bias. (tables 1A–C) To assess the effect of high risk of bias studies on pooled second ACL injury estimates, a sensitivity analysis was performed which included the high risk of bias studies. These results suggest that including high risk of bias studies can exaggerate relative risk estimates away from the null; with the risk of females experiencing an ipsilateral ACL injury decreasing from RR=0.74 (95% CI 0.52 to 1.05) to RR=0.71 (95% CI 0.58 to 0.87). Similarly, female contralateral ACL injury risk increased from RR=1.27 (95% CI 1.00 to 1.60) to RR=1.34 (95% CI 1.07 to 1.70). The risk of bias concerns and noted high heterogeneity (I^2 >50%) seen in most analyses dictate that studies examining second ACL injury outcomes should ensure they adhere to established guidelines (eg, STROBE or CONSORT) in the design and execution of the final manuscript to ensure potential sources of bias are mitigated.84–86 Of note, the Panther Symposium and Consensus Statements have been recently published and should provide an in-depth guide to
What is already known

- Female athletes are at increased risk for sustaining a primary ACL injury compared with males when playing the same sport.

What are the new findings?

- Both sexes are at >20% risk of experiencing a second ACL injury.
- There is a negligible difference in the absolute risk of experiencing a second ACL injury between sexes (risk difference = −0.6%, 95% CI −4.9 to 3.7).
- Females may have a small reduction in the absolute risk of an ipsilateral second ACL injury compared with males (risk difference = −3.4%, 95% CI −6.7% to −0.02%).

Objective clearance based on commonly recommended assessments. We did not standardise the diagnostic criteria of a second ACL injury, which could explain the considerable heterogeneity seen in our per-sex risk estimates. However, we sought to capture all studies with potentially valuable data; and our approach factors in all possible diagnostic and treatment schemes one may experience following a second ACL injury (surgical revision, imaging, clinical examination without imaging, non-operative care and/or KT-1000 arthrometer testing). We only established a minimum follow-up period of 12 months following ACL reconstruction to ensure we captured the early phases of return-to-sport attempts and did not set a follow-up duration limit. We acknowledge there could potentially be studies with second ACL injury data but less than 12 months of follow-up that could have been missed in this review, leading to an underestimation of our estimates. Further, there may be a temporal factor (due to prolonged follow-up) that skewed our results due to continued (or reduced) exposure to risk, but previous literature refutes that association in primary ACL reconstruction. We also recognise that mechanism of injury likely impacts the risk of injury and for some of the proposed mechanisms for sex-based differences. However, few studies reported this information, limiting our ability to factor this into our analysis.

CONCLUSION

Both sexes are at >20% increased risk of experiencing a second ACL injury. Overall, the magnitude of differences in the absolute risk of a subsequent ipsilateral or contralateral ACL injury between sexes appears small and potentially not clinically meaningful. Studies noting high return to sport percentages (>85%) demonstrate that males may be at increased risk of experiencing a subsequent ipsilateral ACL injury compared with females.

Limitations

We removed 36 potentially eligible studies because data were unable to be clarified, thus the pooled estimates and conclusions from this study could have been different due to a selection bias. We acknowledge that all researchers/clinicians involved in those studies were experiencing unforeseen challenges due to the COVID-19 pandemic that could have decreased our response rate and their ability to facilitate our requests. We did not factor in return-to-sport testing or psychological readiness within this analysis. It is plausible there could have been a significant difference in the risk of a second ACL injury had participants received objective clearance based on commonly recommended assessments. We did not standardise the diagnostic criteria of a second ACL injury, which could explain the considerable heterogeneity seen in our per-sex risk estimates. However, we sought to capture all studies with potentially valuable data; and our approach factors in all possible diagnostic and treatment schemes one may experience following a second ACL injury (surgical revision, imaging, clinical examination without imaging, non-operative care and/or KT-1000 arthrometer testing). We only established a minimum follow-up period of 12 months following ACL reconstruction to ensure we captured the early phases of return-to-sport attempts and did not set a follow-up duration limit. We acknowledge there could potentially be studies with second ACL injury data but less than 12 months of follow-up that could have been missed in this review, leading to an underestimation of our estimates. Further, there may be a temporal factor (due to prolonged follow-up) that skewed our results due to continued (or reduced) exposure to risk, but previous literature refutes that association in primary ACL reconstruction. We also recognise that mechanism of injury likely impacts the risk of injury and for some of the proposed mechanisms for sex-based differences. However, few studies reported this information, limiting our ability to factor this into our analysis.
the paper and provided expertise on the subject matter. In addition, Leila Ledbetter, a contributor, provided guidance and assistance with generating the search and providing resources to optimise data management. All authors contributed to the writing, interpretation, critical revision and approval of the manuscript. AP, GSB, TS and JL conceived the research question. JW developed and executed the systematic literature search with input from JL, TS and GSB. AP, JL and GSB performed data extraction. GSB and JL performed statistical analysis and figure generation with input from TS and MP.
