may be especially at risk. However data is scarce and valid comparisons are difficult.

**Objective** To gauge the prevalence of psychological distress and the level of wellbeing amongst UK Olympic and Paralympic programme athletes.

**Design** Cross-sectional questionnaire cohort study.

**Setting** UK Olympic and Paralympic, summer and winter sport athletes.

**Patients (or Participants)** 394 athletes from 29 sports.

**Interventions (or Assessment of Risk Factors)** Between October 2018 and June 2019, participants completed the Kessler Psychological Distress Scale (K10) and the World Health Organisation-Five Well-Being Index (WHO5) questionnaires that indicate levels of psychological distress and subjective wellbeing respectively.

**Main Outcome Measurements** Percentage of athletes reporting low, moderate, high and very high psychological distress. Percentage of athletes reporting high and low wellbeing.

**Results** 24% of athletes reported high or very high psychological distress. More Paralympic than Olympic athletes reported high/very high distress (27% vs 22%). The mean distress score was comparable to age matched population samples. 19% of athletes reported low psychological wellbeing and this was more common in Paralympic athletes than Olympic athletes (23% vs 17%). The mean wellbeing score was comparable to age matched population samples.

**Conclusions** UK Olympic and Paralympic athletes report psychological distress and wellbeing levels similar to aged matched populations. Paralympic athletes have slightly higher levels of distress and lower wellbeing than Olympic athletes and this may relate to disability specific stressors. Sport programmes should have robust mental health support plans that includes regular athlete screening and commensurate support services with additional specific support for athletes with disabilities.

**Background** An abundance of literature on the acute peripheral fatigue (APF)-injury-hypothesis exists without showing uniformity to support or refute this hypothesis. Previous research demonstrated that a decreased balance ability increases injury risk, and APF affects balance performance. Recently, reactive balance tasks were developed to assess balance performance in a more sport related context. However, it is unknown if APF induces changes in brain activity during predefined and reactive balance tasks and how it relates to injury occurrence.

**Objective** To study whether (1) APF fatigue alters brain activity during predefined and reactive balance tasks, and (2) performance on these balance tasks.

**Design** Cross-over design.

**Setting** Primary clinical setting.

**Participant** Twenty healthy participants (age = 24 ± 3 years; height = 1.8 ± 0.1 m; weight = 73.2 ± 11.3 kg).

**Interventions** APF was induced through a 30-second modified Wingate-protocol, while the control task encompassed sitting quietly on the stationary bike for 30s.

**Main Outcome Measurements** Brain activity was measured through electroencephalography during both balance tasks and computed by means of spectral power analysis. The predefined balance task was the Y-balance test (YBT), while the neurocognitive balance test encompassed the reactive balance test (RBT).

**Results** Decreased RBT accuracy was observed after APF (p < 0.05), yet YBT performance and RBT visuomotor reaction time were unaffected. APF induced α- and β-spectral power increments in the prefrontal, motor and posterior parietal cortex during YBT performance (p < 0.05). For the RBT, an α-spectral power increment in the posterior parietal cortex and a β-spectral power increment in the prefrontal cortex were observed due to APF (p < 0.05).

**Conclusions** APF induces different changes in brain activity during predefined and reactive balance tasks. It is likely that different central mechanisms are affected depending on the type of balance task. Further research is needed in an applied setting in order to gain insight in the possible interaction between APF and injury occurrence.
