Background The relationship between head impact dose and observable functional deficits remains unclear. While studies have almost exclusively examined American football athletes, introducing injury prevention measures. Males are more frequently exposed than females, heading rates increase with age, and there is substantial variation between players. Heading is a rare event in the youngest age groups, especially among females.

**Background**
The relationship between head impact dose and observable functional deficits remains unclear. While studies have almost exclusively examined American football athletes, introducing injury prevention measures. Males are more frequently exposed than females, heading rates increase with age, and there is substantial variation between players. Heading is a rare event in the youngest age groups, especially among females.

**Objective**
To investigate if repetitive headers or accidental head impacts in football could cause structural damage to the brain, detected as an increase in serum concentrations of neurofilament light (NfL) or tau proteins.

**Design**
Prospective cohort study.

**Setting**
Elite division football.

**Participants**
Male football players in the Norwegian premier league, including a total of 621 player seasons.

**Independent Variables**
Short- and long-term exposures in football, with and without head impacts.

**Main Outcome Measurements**
Baseline NfL and tau were measured in Norwegian professional football players in pre-season. Then, the effect of short-term exposures (independent variable) was assessed by measuring biomarker levels (dependent variable) after three conditions: (1) high-intensity exercise, (2) repetitive headers, and (3) head-impact incidents in a match. The effect of long-term head impact exposure was assessed by comparing two groups with relative differences in previous concussions and headers at baseline (low vs. high levels).

**Results**
We analyzed 354 samples. Mean (±SD) NfL concentration was 6.8±2.6 pg/mL; mean tau concentration was 1.2±0.7 pg/mL. We observed no short-term effects on NfL after exposure from either of the three conditions. Tau levels rose in response to high-intensity exercise and repetitive headers, but not after accidental head-impact incidents; the highest absolute values were seen 1 h after high-intensity exercise. We did not detect any long-term effects on serum NfL or tau concentrations from previous concussions and headers.

**Conclusions**
NfL and tau in serum were unaffected by head impacts in football, after both short-term and long-term exposure. Importantly, tau levels seem to rise in response to exercise, emphasizing the need for appropriate control groups in future studies. Our findings highlight important characteristics and limitations for using NfL and tau as biomarkers in sports.

**015 BIOMARKERS IN SERUM AFTER HEAD IMPACT EXPOSURE IN FOOTBALL**

1Stian Bahr Sandmo, 2Peter Filipcik, 3Martin Centa, 4Ioazl Hanes, 5Thor Einar Andersen, 6,1Truls M Straume-Næsheim, 7Roald Bahr. 8Oslo Sports Trauma Research Center, Norwegian School of Sport Sciences, Oslo, Norway; 9Faculty of Medicine, University of Oslo, Oslo, Norway; 10Institute of Neuromimmunology, Slovak Academy of Sciences, Bratislava, Norway; 11Department of Orthopedic Surgery, Akershus University Hospital, Lørenskog, Norway; 12Department of Orthopedic Surgery, Haugesund Rheumatism Hospital, Haugesund, Norway

**Background**
The link between head-impact exposure in football and neurological sequelae remains controversial. Blood-based biomarkers can provide valuable information in traumatic brain injuries, reflecting e.g. axonal damage.

**Objective**
To investigate if repetitive headers or accidental head impacts in football could cause structural damage to the brain, detected as an increase in serum concentrations of neurofilament light (NfL) or tau proteins.

**Design**
Prospective cohort study.

**Setting**
Elite division football.

**Participants**
Male football players in the Norwegian premier league, including a total of 621 player seasons.

**Independent Variables**
Short- and long-term exposures in football, with and without head impacts.

**Main Outcome Measurements**
Baseline NfL and tau were measured in Norwegian professional football players in pre-season. Our findings highlight important characteristics and limitations for using NfL and tau as biomarkers in sports.
Background Understanding the risk of concussion and how this injury occurs in rugby union match play can inform future injury reduction strategies. This has been investigated in professional rugby but not in the UK elite level pathway.

Objective Describe the incidence of concussion and characteristics of tackles resulting in concussion in British University rugby union.

Design A one-season prospective cohort study; team medical staff reported match play concussions. Matches were filmed and tackle-related concussions were analysed alongside 796 non-injurious ‘control’ tackles.

Participants Eight teams (341 players).

Independent variables Match exposure.

Main Outcome Measurements Injury incidence and characteristics of tackles associated with concussion.

Results There were 43 concussions in 154 team games; incidence was 14.0 per 1000 player match hours (95% CI: 10.1–18.8) and mean absence was 23 days (95% CI: 16.1–29.9). Thirty-four (79%) concussions occurred in the tackle; 22 by the tackling ball carrier and 12 by the ball carrier. Twenty-five tackles resulting in concussion could be conclusively identified on video (tackler: 16; ball carrier: 9). For control tackles, 5% resulted in initial impact to the head/neck and 18% to the shoulders of the ball carrier compared with tackles resulting in concussions to the ball carrier [head/neck, 3 (33%); shoulder, 2 (22%)] or tackler [head/neck, 2 (13%); shoulder, 3 (19%)]. For tackle concussions, 3 (19%) involved head-to-head contact (2% of control tackles) and 4 (25%) involved head-to-shoulder contacts (6% of control). The ball carrier was travelling at high speed for 67% of ball carrier concussions, compared with 29% for control tackles.

Conclusions Concussion incidence in high-level university rugby union is slightly lower than professional rugby with most concussions occurring in the tackle. Lowering tackle height may help reduce concussion for the ball carrier and the tackler should prioritise head positioning away from the ball carrier’s head and shoulders.

Design Randomised controlled trial, single blinded

Setting Youth handball players (16–18 yrs)

Participants Four youth handball teams (three female, one male, 57 players, mean age 17.1 yrs) were randomly selected from eligible teams in the Oslo region, and randomized to an intervention group (28 players) or control group (29 players).

Interventions The Oslo Sports Trauma Research Center shoulder injury prevention program was implemented during regular handball warm-up three times a week for 18 weeks in the intervention group.

Main Outcome Measurements The main outcome variable was the between-group difference in ER strength and IR ROM change from baseline to post intervention. Isometric ER strength was measured with a handheld dynamometer and IR ROM with a digital goniometer.

Results Mean dominant shoulder isometric ER strength increased significantly both in the intervention (10%) and the control group (6%) during the intervention, but there was no significant group by time interaction (group difference: 0.06 N/kg [95% CI: −0.04 to 0.17]). IR ROM did not change in either group during the intervention.

Conclusions The Oslo Sports Trauma Research Center shoulder injury prevention program did not affect the risk factors ER strength and IR ROM. The preventive effect of the program must therefore be due to other factors.

Background High shoe-surface friction is a proposed risk factor for ‘non-contact’ lateral ankle sprain (LAS) injuries. Spraino® is a novel product that minimizes friction at the lateral edge of the shoe, thereby potentially mitigating the risk.

Objective To determine preliminary effect and safety of Spraino® when used to prevent LAS injury among indoor sport athletes.

Design A double-blinded, prospective, two-arm pilot randomised controlled trial (RCT). Participants were allocated (1:1) to Spraino® or to a ‘do-as-usual’ control group. The random allocation was concealed for investigators and participants. Group allocations were outcome-assessor-blinded.

Setting Indoor sports clubs competing at divisional- or league level in handball, handminton and basketball in Denmark.
