Conclusions Hamstring strength endurance and fatigability were both justified as potential risk factors of re-injury and should be integral parts of future rehabilitation programmes and prognostic screening.

HAOS OR CHAOS? THE PROGNOSTIC VALUE OF THE HAMSTRING OUTCOME SCORE (HAOS) TO PREDICT THE RISK OF HAMSTRING INJURY

Background Hamstring injury incidence remains high among male soccer players. One of the reasons is low adherence for effective hamstring injury prevention programs. Insight in injury risk can contribute to better adherence for injury prevention measures. The hamstring outcome score (HaOS) might provide an insight in injury risk.

Objective To determine the relation between the HaOS and both previous and new hamstring injuries in male amateur soccer players, and to determine the prognostic value of the HaOS to predict the risk of hamstring injuries.

Design Data was collected during a large cluster-RCT investigating a hamstring injury prevention program.

Setting This study was executed during one competition (2016–2017) in 32 first class amateur soccer teams.

Participants 400 adult male amateur soccer players started the study.

Assessment of risk factors The participants filled in a baseline-questionnaire consisting of injury history and the HaOS. During one full competition hamstring injuries were registered prospectively.

Main outcome measurements Previous hamstring injuries, new hamstring injuries and the HaOS (total score and subdomains) were considered in this study.

Results In 356 players, a significant relation was found between the HaOS (total score and all HaOS subdomain scores) and previous and new hamstring injury (F=17.4, p<0.0001 and T=3.59, p=0.001, respectively). This indicated that more hamstring injuries during the previous season was related to lower scores on the HaOS and lower HaOS scores correspond with more new hamstring injuries. With a cut-off score of 80% on the HaOS, logistic regression models showed a probability of 11%, 18% and 28% on a new hamstring injury in players with 0.1 or 2 previous injuries, respectively.

Conclusion The HaOS is significantly associated with both previous and new hamstring injury and might be a useful tool to provide insight in players’ hamstring injury risk when used in combination with injury history.
sprinting capacity. This implicates that introducing eccentric hamstring strengthening during pre/early season seems relevant as this may both increase sprinting performance and mitigate the risk of HI during the in-season.

161 HIGH CONCUSSION RATE AMONGST SOUTH AFRICAN UNIVERSITY RUGBY STUDENT TOURNAMENT

James Craig Brown, 1,2 Lindsay Starling, 3,4 Keith Stokes, 1,2 Pierre Viviers, 1,2 Sean Surmon, 1,2 Keith Derman. Institute of Sport and Exercise Medicine, Division of Orthopaedics, Department of Surgical Sciences, Stellenbosch University, Cape Town, South Africa; 1IOC Research Centre, South Africa, Cape Town, South Africa; 3Department for Health, University of Bath, Bath, UK; 4Rugby Football Union, London, UK; 5Maties Sport, Stellenbosch University, Stellenbosch, South Africa

Background Of all injuries common to collision sports, concussions have received the most attention due to the potentially negative cognitive effects in the short- and long-term. Stellenbosch Rugby Football Club (‘Maties’), the official rugby club of Stellenbosch University, represents one of the world’s largest non-professional Rugby clubs, making this an ideal cohort for community level injury surveillance.

Objective To describe the incidence and events associated with concussion in this large non-professional homogenous cohort.

Design A one-season prospective cohort injury surveillance study.

Setting Students (young adults) athletes competing in the internal (‘Koshuis’) tournament of the Maties Rugby Club in 2018.

Patients (or Participants) All 807 male players registered for the Koshuis tournament in 2018, which was comprised of 101 matches and 2,915 of exposure hours. The average age, height and weight of this cohort was 20±2 years, 182±7 cm and 88±14 kg, respectively.

Interventions (or Assessment of Risk Factors) Recording of all injuries, and factors associated with injury, according to the consensus statement for injury recording in rugby.

Main Outcome Measurements Overall, there were 89 time-loss injuries, which equated to an injury rate of 31 per 1000 match hours (95% confidence intervals [CIs]: 24–37), or about one injury per match. The most common injury diagnosis was ‘concussion’ (n=27 out of 90 injuries, 30%), at a rate of 9 per 1000 match hours (95% CIs: 6–12).

Results The three most common mechanisms of concussion in the present study were performing a tackle (33%), accidental collision (30%) and being tackled (11%).

Conclusions Concussion was the most common injury in this population, at a rate that was six times higher than a comparable cohort in the UK. Future studies should try to explain this higher rate and subsequently reduce these concussions.

162 ABSTRACT WITHDRAWN

163 GENDER DIFFERENCES IN HEAD IMPACT RATE AND MECHANISM IN HIGH SCHOOL LACROSSE

Declan Patton, 1,2 Colin Huber, 1,3 Valerie Lalio, 1,4 Catherine McDonald, 1,5 Kristy Arbogast.

Background There is debate as to whether protective headwear should be mandated in female lacrosse; however, a lack of quantitative evidence exists regarding the effectiveness of, and case for, protective headwear in female lacrosse.

Objective To compare head impacts in male and female lacrosse in terms of rate recorded by headband-mounted sensors and mechanism determined by video analysis.

Design Prospective observational study.

Setting One season of suburban high school female (12 games) and male (15 games) lacrosse competition.

Participants Adolescent female (n=15) and male (n=33) lacrosse players.

Main Outcome Measurements Head impact rate as calculated by the number of video-confirmed head impacts above 16 g recorded by SIM-G (Triax Technologies) headband-mounted impact sensors divided by the number of player-games during one season. Mechanism of impact (i.e. player contact, fall, stick-to-head or ball-to-head) determined by detailed video analysis of sensor-recorded events.

Results For male lacrosse, 226 head impacts were recorded during 272 player-games for an impact rate of 0.83 impacts per player-game. The most common mechanism for head impacts to male lacrosse players was player contact (57%) followed by stick-to-head (27%), falls (15%) and ball-to-head (2%). For female lacrosse, 7 head impacts were recorded during 109 player-games for an impact rate of 0.66 impacts per player-game. Of the seven head impacts to female lacrosse players, three were player contact (43%), three were stick-to-head (43%) and one was a fall (14%).

Conclusions The impact rate for female lacrosse players is less than 8% of the rate for male lacrosse players, which suggests that head impacts in female high school lacrosse are rare. However, nearly half of the head impacts in female lacrosse were stick-to-head, for which protective headwear may reduce the risk of injury. Therefore, further investigation of the association between head impact mechanism and injury in female lacrosse is required.

164 NORMATIVE BASELINE SCATS SCORES IN A POPULATION OF UNITED STATES OLYMPIC ATHLETES
