ABSTRACT

For over two decades, the Concussion in Sport Group has held meetings and developed five international statements on concussion in sport. This 6th statement summarises the processes and outcomes of the 6th International Conference on Concussion in Sport held in Amsterdam on 27–30 October 2022 and should be read in conjunction with the (1) methodology paper that outlines the consensus process in detail and (2) 10 systematic reviews that informed the conference outcomes. Over 3½ years, author groups conducted systematic reviews of predetermined priority topics relevant to concussion in sport. The format of the conference, expert panel meetings and workshops to revise or develop new clinical assessment tools, as described in the methodology paper, evolved from previous consensus meetings with several new components. Apart from this consensus statement, the conference process yielded revised tools including the Concussion Recognition Tool-6 (CRTC6), Sport Concussion Assessment Tool-6 (SCAT6), Child SCAT6, and Child SCAT6 and assessment tools to assist in the detection and assessment of SRC, including the Concussion Recognition Tool-6 (CRTC6), Sport Concussion Assessment Tool-6 (SCAT6), Child SCAT6, Sport Concussion Office Assessment Tool-6 (SCOAT6), and Child SCOAT6. This consensus process also integrated new features including a focus on the para athlete, the athlete’s perspective, concussion-specific medical ethics and matters related to both athlete retirement and the potential long-term effects of SRC, including neurodegenerative disease. This statement summarises evidence-informed principles of concussion prevention, assessment and management, and emphasises those areas requiring more research.

INTRODUCTION

This Amsterdam 2022 International Consensus Statement on Concussion in Sport (Statement) builds on previous Concussion in Sport Group (CISG) statements with the goal of updating current recommendations for sport-related concussion (SRC) through an evidence-informed consensus methodology. The purpose of this Statement is to provide a summary of the evidence and practice recommendations based on science and expert panel consensus recommendations at the time of the conference. Additional outputs of the consensus process include freely available evidence-informed tools to assist in the detection and assessment of SRC, including the Concussion Recognition Tool-6 (CRTC6), Sport Concussion Assessment Tool-6 (SCAT6), Child SCAT6, Sport Concussion Office Assessment Tool-6 (SCOAT6), and Child SCOAT6. Apart from this Statement, in the interest of knowledge translation, the tools are free to distribute in their original formats. This Statement is developed for the healthcare professional (HCP) involved in the care of athletes at risk of SRC or who have sustained a suspected SRC at any level of sport (ie, recreational to professional). The authors recognise that differences in geography, healthcare structure and culture are important considerations when implementing the principles presented. Thus, this Statement provides recommendations that can be adapted for different sport, clinical and cultural environments and is not meant to be used as a prescriptive guideline. We also recognise that the science of concussion continues to evolve, and the Amsterdam Statement reflects the state of the evidence at the time of the Consensus Conference and will need to be updated as new scientific information emerges. Also included are recommendations for future research where notable gaps in the literature have been identified. Although this Statement provides recommendations and is a summary of the consensus process, it should be read in combination with the 10 systematic reviews and methodology papers that informed the consensus process and outcomes.

MEDICOLEGAL CONSIDERATIONS

This Statement is not intended as a clinical practice directive or legal standard of care and should not...
Key points

⇒ The Amsterdam 2022 International Consensus Statement on Concussion in Sport summarises published evidence at the time of the conference and should be read together with the 10 systematic reviews and the methodology paper.
⇒ Content and methodological advances were made in the consensus process including anonymous voting, summaries of alternate viewpoints, declarations of conflicts of interest in the open conference, plus inclusion of the athlete voice, para sport considerations and ethical perspectives.
⇒ The Consensus in Sport Group definition of concussion was updated while work continues toward a unified conceptual and operational definition.
⇒ Sport-specific strategies recommended as concussion prevention interventions include policy or rule changes reducing collisions, neuromuscular training in warm-ups, mouthguard use in ice hockey and implementation of optimal concussion management strategies to reduce recurrent concussion rates.
⇒ The Concussion Recognition Tool-6 (CRT6), Sport Concussion Assessment Tool-6 (SCAT6) and Child SCAT6 provide updated iterations of the acute sport-related concussion (SRC) tools best used in the first 72 hours (and up to 1 week) after injury. New office tools, the Sport Concussion Office Assessment Tool-6 (SCOAT6) and Child SCOAT6, were designed to better guide evaluation and management in an office setting from 72 hours after injury and for serial evaluations in the following weeks. The overlap between the SCAT6 and SCOAT6 is intentional and designed to facilitate easy transitions across tools.
⇒ The results of computerised neurocognitive tests should be interpreted in the context of broader clinical findings and are not to be used in isolation to inform management or diagnostic decisions.
⇒ Advanced neuroimaging, fluid-based biomarkers, genetic testing and emerging technologies are valuable research tools for the study of concussion but not yet suited for routine use in clinical practice.
⇒ Return-to-learn and return-to-sport strategies have been updated based on evolving evidence.
⇒ Strong evidence exists regarding the benefits of physical activity and aerobic exercise treatment as early interventions.
⇒ Cervicothoracic rehabilitation is indicated for athletes with neck pain, headaches, dizziness and/or balance problems.
⇒ Individuals with persisting symptoms (ie, symptom duration >4 weeks) should be evaluated with a multimodal clinical assessment including the use of standardised and validated symptom rating scales.
⇒ The potential long-term effects of SRC and repetitive head impacts are areas of ongoing public health interest and concern among both healthcare professionals and the general public. It is proposed that a working group representing multiple disciplines and perspectives be established to guide appropriate research in this area.
⇒ Decisions regarding retirement or discontinuation from contact or collision sports are complex, multifaceted and should be individualised to consider patient, injury, sport-specific, ethical and psychosocial factors. A comprehensive multidisciplinary clinical evaluation is often necessary to inform decisions.
⇒ Limited evidence exists on SRC in patients aged 5–12 years.

Key points

⇒ Concussion diagnosis and management in para athletes is challenging with limited data, requiring further research and dedicated clinical recommendations that consider a range of impairments.
⇒ Future research and consensus processes for concussion in sport should continue to evolve with an inclusive and interdisciplinary approach.

METHODS

The proposed conference process was developed by the Scientific Committee and informed by the British Journal of Sports Medicine (BJSM) author guidelines for consensus statements,1 built on previous methodology2 and consensus processes in other fields.3–7 The detailed methodology for the consensus process is outlined in figure 1 and explained in detail in a separately published paper.8 Electronic voting (e-voting) by the expert panel on the content of this Statement is reflected in figure 2. Consensus agreement was defined a priori as 80% majority. Dissenting viewpoints are also presented in figure 2. All original research studies informing the recommendations in this Statement are cited in the associated systematic reviews.

Equity, diversity and inclusion statement

The 31 expert panelists represented multiple disciplines from nine different countries (Australia, Canada, Finland, Japan, South Africa, USA, UK, Switzerland, Czech Republic), six were women, two identified as non-White and one was a former Paralympian. Experts were all senior clinicians and researchers across multiple disciplines and areas of expertise, but several early career researchers were involved as authors in the systematic reviews. Although more expansive than previous consensus processes, the need for greater geographical and demographic diversity and inclusion among the expert panel and authors has been identified by the Scientific Committee, and a postconference survey was conducted to help determine equity, diversity and inclusion (EDI) focus areas.

SPORT-RELATED CONCUSSION

The Consensus Statement from the Berlin 2016 International Conference on Concussion in Sport1 refers to the ‘11 Rs’ of SRC (RECOGNISE, REDUCE, REMOVE, REFER, RE-EVALUATE, REST, REHABILITATE, RECOVER, RETURN-TO-LEARN/RETURN-TO-SPORT, RECONSIDER and RESIDUAL EFFECTS) to provide a logical flow of clinical concussion
**RECOGNISE: DEFINITION OF SPORT-RELATED CONCUSSION**

The CISG proposed a conceptual definition of SRC in 2001. This definition has undergone updates and modifications at subsequent CISG meetings, with the most recent being in Berlin in 2016. In preparation for the Amsterdam International Consensus Conference on Concussion in Sport, the Scientific Committee considered that the Berlin definition required modification to align with more recent scientific evidence relating to advances in our understanding of SRC pathophysiology. The conceptual definition, accepted as a majority decision (78.6%) but not reaching an 80% consensus, is:

*Sport-related concussion is a traumatic brain injury caused by a direct blow to the head, neck or body resulting in an impulsive force being transmitted to the brain that occurs in sports and exercise-related activities. This initiates a neurotransmitter and metabolic cascade, with possible axonal injury, blood flow change and inflammation affecting the brain. Symptoms and signs may present immediately, or evolve over minutes or hours, and commonly resolve within days, but may be prolonged.*

No abnormality is seen on standard structural neuroimaging studies (computed tomography or magnetic resonance imaging T1- and T2-weighted images), but in the research setting, abnormalities may be present on functional, blood flow or metabolic imaging studies. Sport-related concussion results in a range of clinical symptoms and signs that may or may not involve loss of consciousness. The clinical symptoms and signs of concussion cannot be explained solely by (but may occur concomitantly with) drug, alcohol, or medication use, other injuries (such as cervical injuries, peripheral vestibular dysfunction) or other comorbidities (such as psychological factors or coexisting medical conditions).

The conceptual definition above does not provide specific diagnostic criteria. Diagnostic criteria using an operational definition for mild traumatic brain injury have recently been published. They were developed by the Mild Traumatic Brain Injury Task Force of the American Congress of Rehabilitation Medicine (ACRM) Brain Injury Special Interest Group through rapid evidence reviews and a Delphi expert consensus process. A unified conceptual and operational definition remains a desirable aim of both the CISG and ACRM.

**REDUCE: PREVENTION OF CONCUSSION**

A focus on primary concussion prevention will mitigate the burden of injury, risk of recurrent injury and potential for persisting symptoms. Sport policy-makers and HCPs are encouraged to identify and optimise SRC prevention strategies in their environment. Implementing primary prevention of SRC across all levels of sport is a priority that can have a significant public health impact. In the past 5 years, there has been a threefold increase in studies examining the effectiveness of SRC prevention that have assessed policy and rule changes, personal protective equipment, training strategies and management. Studies including children and adolescents represented over 60% of studies evaluating SRC prevention strategies.
Consensus statement

Figure 2  Expert panel voting for content included in the 2022 Amsterdam Consensus Statement. Dissenting opinion: “In this setting, concussion needs to be defined based on pathological constructs, not clinical ones, as the symptoms of concussion are non-specific. There is a differential diagnosis for concussion presentations/symptoms that must be considered. Using a definition schema based only on symptoms would greatly increase false-positive diagnoses and negatively affect patient care. “Recommend retaining a timed version of the months of the year in reverse. “Make no
changes. Must not rely on daily schedule protocol for RTS. Suggest a change to stage 3. Do not include CTE because it is a neuropathological diagnosis. Notes: *'Agree' or 'Agree with minor revisions' votes were considered as consensus support for the presented text. **Twenty-nine members of the expert panel were in attendance in Amsterdam; one was absent due to illness; the moderator did not vote making the total number to 27 for the last two topics. ***Thirty members of the expert panel attended the follow-up Zoom meeting (Topics 9. RTS update and 10. Long-term effects); again, the session moderator did not vote making the total number of votes 29. ACRM, American Congress of Rehabilitation Medicine; COI, Conflict of interest; CTE, chronic traumatic encephalopathy; FEI, Fédération Equestre Internationale; FIA, Fédération Internationale de l’Automobile; FIFA, Fédération Internationale de Football Association; IHIF, International Ice Hockey Federation; IOC, International Olympic Committee; RTL, return-to-learn; RTS, return-to-sport; SCAT, Sport Concussion Assessment Tool; SCOTA6, Sport Concussion Office Assessment Tool-6; VOMS, Vestibular-Occular Motor Screen; WR, World Rugby.

Policy or rule changes
The policy disallowing body checking in child or adolescent ice hockey reduced the rate of concussion in games by 58%. Further, the policy had no unintended consequences, as a greater number of experience in body checking leagues did not reduce concussion rates in adolescent hockey leagues that allow body checking across all levels of play. Evidence supports that policies disallowing body checking in youth ice hockey prevent concussions, and these policies should be applied for all levels of children’s ice hockey and most levels of adolescent ice hockey.

Policy and rules limiting the number and duration of contact practices, intensity of contact in practices and strategies restricting collision time in practices in American football across all age groups have led to an overall 64% reduction in practice-related concussions and to reduced head impact rates. Future research should focus on the prospective evaluation of relevant sport-specific policy and rule modifications aimed to reduce SRCs and head impact rates. Limiting contact practice in American football and US football should inform related policies and recommendations for all levels of play.

Personal protective equipment
Mouthguards were associated with a 28% reduced concussion rate in ice hockey across all age groups, indicating that mouthguards should be mandated in child and adolescent ice hockey and supported at all levels of play. Evaluation of headgear in non-helmeted contact and collision sport requires more research to inform headgear recommendations.

Training strategies
Participation in on-field neuromuscular training (NMT) warm-up programmes completed at least three times per week has been associated with a lower rate of concussion in Rugby Union (rugby) across all age groups. NMT warm-up programmes are recommended in rugby to reduce concussion rates. The effect of NMT programmes to reduce concussion rates specifically has not been assessed in other sports. While extensive evidence exists to support the effectiveness of NMT warm-up programmes in reducing all injuries and lower extremity injuries, more research is needed for NMT warm-up programmes in women and other team sports specifically targeting exercise components aimed to reduce concussion rates.

Concussion management
Optimal concussion management strategies including implementing laws and protocols (eg, mandatory removal from play following actual or suspected concussion; requirements to receive clearance to return-to-play from an HCP; and education of coaches, parents and athletes regarding concussion signs and symptoms) are associated with a reduction in recurrent concussion rates.

The panel unanimously supported the following recommendations for prevention:

► Mouthguard use should be supported in child and adolescent ice hockey.
► Policy disallowing body checking should be supported for all children and most levels of adolescent ice hockey.
► Strategies limiting contact practice in American football should inform related policies and recommendations for all levels.
► NMT warm-up programmes are recommended, based on research in rugby, and more research is needed for female athletes and in other team sports specifically targeting exercise components aimed to reduce concussion rates.
► Policy supporting optimal concussion management strategies to reduce recurrent concussion rates is recommended.

REMOVE: SIDELINE EVALUATION
The recognition of concussion is the first step to initiating the management of SRC. Removal of a player from the field of play should be done if there is suspicion of a possible concussion to avoid further potential injury. This may be based on a player’s symptoms or signs observed by other players, medical staff or officials (on the field or video). Signs that warrant immediate removal from the field include actual or suspected loss of consciousness, seizure, tonic posturing, ataxia, poor balance, confusion, behavioural changes and amnesia.

Players exhibiting these signs should not return to a match or training that day, unless evaluated acutely by an experienced HCP with a multimodal assessment (as noted below) who determines that the sign was not related to a concussion (eg, the player has sustained a musculoskeletal injury and thus unable to balance). Maddocks’ questions remain part of a useful and brief on-field screen for athletes >12 years of age without clear on-field signs of a concussion; incorrect answers warrant a more comprehensive off-field evaluation as does any clinical suspicion of concussion. Symptoms and signs of a concussion may evolve over minutes, hours or days. Whether acute concussion is suspected or confirmed, the player should be serially re-evaluated in the coming hours and days.

Designed to assist in the multimodal evaluation of athletes, previous versions of the SCAT have been shown to be most effective in discriminating between concussed and non-concussed athletes within 72 hours of injury and up to 5-7 days postinjury, although their clinical utility appears to diminish after 72 hours. Ceiling effects were apparent on the 5-word list learning and concentration subtests. Use of more challenging tests, including the 10-word list, was recommended. Differences were found among the 3 forms of the list learning task suggesting that the forms are not equivalent in difficulty. Test–retest data revealed limitations in temporal stability across subtests. Except for the symptom scale, these tools may not be appropriate for use in the return-to-sport (RTS) decision-making process beyond 7 days.
postinjury. Empirical data are limited in some sports and for preadolescent, female and para athletes, suggesting a need for more globally diverse research including athletes from under-represented groups.

The bullet points below present the recommendations and considerations for modifying the previous iteration of the SCAT to develop the SCAT6 and Child SCAT6. The Child SCAT6 should be used in patients aged 8–12 years. The final determinations of content included in the SCAT6 and Child SCAT6 were based on findings from the systematic review as well as expert panel discussions highlighting the importance of the scientific evidence while balancing pragmatic considerations for the development and utility of the tools. For example, some expert panel members were hesitant to make changes that would invalidate existing normative data. Factors such as applicability and time constraints that exist during the acute/sideline evaluation guided considerations. The initially proposed changes to the SCAT5 that were voted on did not reach a consensus in the first round of voting. Following further discussions, subsequent voting on individual subcomponent tests to add/remove from the SCAT5 occurred to incorporate a specific test as ‘recommended’ or ‘optional’. Each proposed change, except for the Vestibular-Ocular Motor Screen (VOMS), had >80% agreement to include as either recommended or optional (see figure 2 for details). As a result, the VOMS was not included in the SCAT6. Further, detailed deliberations regarding the development of the SCAT6 occurred during a dedicated Tools Meeting on day 4 of the Amsterdam Conference. As with previous versions, the SCAT6 and Child SCAT6 require validation.

The following recommendations were made based on the systematic review and subsequent expert panel discussions:

- Explore the development of alternate tools for serial evaluation in the office setting.
- Improve psychometric properties: longer word list (eg, 12- or 15-word list) and remove the 5-word list.
- Further examine form differences on existing 10-word lists and consider the use of regression-based norms.
- Create a cognitive composite score to improve test–retest reliability and reduce false positives.
- Add digits (ie, increase the longest string by two digits) to the digit span backward subtest to reduce ceiling effects.
- Revise months backward to include a component of timed information processing.
- Add timed dual gait tasks.
- Implement tests and/or procedures to assess the performance validity of baseline testing.
- Add a more robust set of visible signs to the SCAT6/Child SCAT6/CRT6, including: Falling with no protective action, tonic posturing, impact seizure, ataxia/motor incoordination, altered mental status and blank/vacant/dazed look.
- Support serial SCAT6/Child SCAT6 assessments after an athlete is removed from play, for example, half-time after the game and 24–48 hours after injury.

Typically, the process of conducting a multimodal screen to evaluate a potential concussion takes at least 10–15 min. Sport organisations are strongly advised to allow for at least that amount of time for an adequate evaluation and to accommodate such an assessment off-field, preferably in a quiet area away from the pressures and scrutiny of match play. For athletes with potential signs of a concussion, any screening assessment short of a multimodal evaluation of symptoms, signs, balance, gait, neurological and cognitive changes associated with a potential concussion may be inadequate to allow continued sports participation. Sports whose rules currently do not facilitate such evaluations should strongly consider enacting rule changes in the interest of player welfare.

Based on the research on previous iterations, the SCAT has optimum utility in the first 72 hours and up to a week after injury. The SCAT6 or Child SCAT6 tools are intended for multimodal and serial evaluations conducted in the office after 72 hours.

**RE-EVALUATE: THE OFFICE ASSESSMENT**

The purpose of developing a Sport Concussion Office Assessment Tool (SCAT6/Child SCAT6) was to give HCPs a standardised, expansive and age-appropriate clinical guide to a multidomain evaluation in the subacute phase (72 hours to weeks postinjury), with a view to guide individualised management.

In some cases, a SCAT/Child SCAT may have been performed close to the time of acute injury, in which case the comparison of recorded symptoms and signs will be of value. In other scenarios, the SCAT6/Child SCAT6 may be the initial assessment used to inform SRC diagnosis and management.

The SCAT6/Child SCAT6 is designed to assist clinicians in assessing important clinical manifestations influencing the presentation of concussion, identifying areas for potential individualised therapeutic interventions, directing the need for specialist referral(s) and monitoring recovery.

The SCAT6/Child SCAT6 does not replace the HCP’s clinical acumen; rather, it provides a standardised framework that can be adapted to help inform the clinical evaluation in an office setting. The Child SCAT6 should be used in patients aged 8–12 years, while the SCAT6 should be used in patients 13 years and older. These tools are meant to be used within the expertise and areas of competency of the clinician. We recognise that consultation time, available resources and practitioner experience will vary. As with earlier versions of the SCAT, the SCAT6 requires evaluation, including an appraisal of its psychometric properties, validation (including at different time points postinjury, in different populations, cultures and languages) and modification with time and evolving evidence.

The athlete’s history of concussions, how each concussion was managed and recovery time should be noted. Medical and psychological diagnoses that may modify the presentation or recovery such as migraine, other headache disorder, anxiety and depression should be documented. The SCAT6/Child SCAT6 symptom scale mirrors that of the SCAT6/Child SCAT6. Preinjury (baseline), sideline or acute symptom scores, if available, should be used for comparison.

The following were recommended to be included in an official evaluation of SRC (details included in the SCAT6):

- Word recall and Digit Backwards tests: The 10-word immediate recall and digit string backwards tests should be used. If the athlete finds the word recall task too easy (eg, exhibits a ceiling effect), a 15-word list may be used.
- Measurement of systolic and diastolic blood pressure as well as heart rate taken in two positions:
  - Supine position, rest for 2 min and take measurements.
  - Follow with the standing position, measure again after 1 min.

Symptoms brought on by a change in postural position (eg, lightheaded, dizzy or motion sensation) should be noted in the patient’s record.

- Evaluation of cervical spine range of motion, muscle spasm and palpation for segmental or midline tenderness.
REST AND EXERCISE

The best available evidence shows that recommending strict rest until the complete resolution of concussion-related symptoms is not beneficial following SRC. Relative (not strict) rest, which includes activities of daily living and reduced screen time, is indicated immediately and for up to the first 2 days after injury. Individuals can return to light-intensity physical activity (PA), such as walking that does not more than mildly exacerbate symptoms, during the initial 24–48 hours following a concussion.

Clinicians are encouraged to recommend early (after 24–48 hours) return to PA as tolerated (eg, walking or stationary cycling while avoiding the risk of contact, collision or fall).

The best data on cognitive exertion show that reduced screen use in the first 48 hours after injury is warranted but may not be effective beyond that.

Individuals can systematically advance their exercise intensity based on the degree of symptom exacerbation experienced during the prior bout of aerobic exercise.

HCPs with access to exercise testing can safely prescribe a subthreshold aerobic exercise treatment within 2–10 days after SRC, based on the individual’s heart rate threshold (HRt) that does not elicit more than mild symptom exacerbation during the exercise test (eg, ‘mild’=testing stops with an increase of more than two points on a 0–10 point scale when compared with the pre-exercise resting value). Subsymptom threshold aerobic exercise treatment can be progressed systematically based on the determination of the new HRt on repeat exercise testing (every few days to every week).

Athletes may continue/advance the duration and intensity of PA or prescribed aerobic exercise provided there is no more than mild (increase of no more than 2 points vs the pre-exercise value) and brief (<1 hour) exacerbation of their concussion-related symptoms.

PA/exercise and cognitive exertion should be stopped if concussion symptom exacerbation is more than mild and brief and may be resumed once symptoms have returned to the prior level. Clinicians should inform their patients that mild symptom exacerbation during PA, prescribed aerobic exercise treatment or during cognitive activity is typical brief (under an hour) and does not delay recovery. Prescribed subsymptom threshold aerobic exercise within 2–10 days of SRC is effective for reducing the incidence of persistent symptoms after concussion (symptoms >1 month) and is also effective for facilitating recovery in athletes suffering from symptoms lasting longer than 1 month. Importantly, individuals should be advised to avoid the risk of reinjury (ie, contact, collision or fall) until determined by a qualified HCP to be safe for higher risk activities.

Sleep disturbance in the 10 days after SRC is associated with an increased risk of persisting symptoms and may warrant evaluation and treatment.

REFER

Where the clinical environment allows, referral to clinicians with specialised knowledge and skills in concussion management should be considered for the targeted treatment of persisting symptoms. This may include the management of cervicogenic symptoms, migraine and headache, cognitive and psychological difficulties, balance disturbances, vestibular signs and ocular motor manifestations.

Persisting symptoms (>4 weeks across all age groups) may be pre-existing, concussion-related or both. Serial multimodal evaluation using a tool such as the SCOAT6/Child SCOAT6, and additional detailed clinical evaluations for specific symptoms (eg, headaches, dizziness, cognition) can help guide referrals. Specialist clinicians whose diagnostic assessments, clinical evaluations and treatment interventions for SRC may be of use as part of a clinician network may vary depending on the region, practice culture and local healthcare environment, and available areas of competency and expertise. This SRC clinician network may include sports medicine physicians, athletic trainers/therapists, physiotherapists, occupational therapists, sports chiropractors, neurologists, neurosurgeons, neuropsychologists, ophthalmologists, optometrists, physiatrists, psychologists and psychiatrists.

Specific recommendations include:

The term ‘persisting symptoms’ is used for symptoms that persist >4 weeks across children, adolescents and adults.
Persisting symptoms can be assessed using standardised and validated symptom rating scales. However, evidence-based recommendations regarding the use of other specific tests or measures in the clinical diagnosis of persisting symptoms in any age group are not possible based on existing research.\(^{37}\)

A multimodal clinical assessment, ideally by a multidisciplinary team, is indicated to characterise individuals with persisting symptoms, including the types, pattern and severity of symptoms, and any associated conditions or other factors that may be causing or contributing to the symptoms. Symptoms attributed to concussion are non-specific, commonly also reported by healthy individuals and those with conditions other than concussion, and can be exacerbated by a variety of biopsychosocial factors aside from concussion, which should be assessed in the context of persisting symptoms. Other problems may exist prior to injury (but can be exacerbated by a concussion), co-occur with persisting symptoms or mimic persisting symptoms but do not arise from concussion. Common considerations in the context of persisting symptoms include mental health issues; learning or attention difficulties; visual, oculomotor, cervical and vestibular problems; headache disorders and migraine; sleep disturbance; dysautonomia, including orthostatic intolerance and postural orthostatic tachycardia syndrome; and pain.

**REHABILITATION**

If dizziness, neck pain and/or headaches persist for more than 10 days, cervicovestibular rehabilitation is recommended.\(^{38}\) If symptoms persist beyond 4 weeks in children and adolescents, active rehabilitation and collaborative care may be of benefit. For children, adolescents and adults with dizziness/balance problems, either vestibular rehabilitation or cervicovestibular rehabilitation may be of benefit. The inclusion of subsympptom threshold aerobic exercise (as outlined above) in combination with other treatments should be considered. In the case of a recurrence of symptoms when progressing through the return-to-learn (RTL) or return-to-sport (RTS) strategies, re-evaluation and referral for rehabilitation may be of benefit to facilitate recovery.\(^{38}\)

Rehabilitation may be targeted to individual symptoms or maybe more general and focus on overall recovery. The effects of combinations of rehabilitation, optimal timing for initiation of rehabilitation and modifying factors (such as age and sex) are not yet well established and require further evaluation.

**RECOVERY**

**Assessment of clinical recovery**

The determination of clinical recovery was found to vary across research studies and healthcare practices and depended on the research question under evaluation. Primary recovery outcomes include symptom ratings, specific clinical tests or groups of tests and functional domains such as RTL and RTS. In some investigations, only one clinical recovery outcome is reported, and these different outcomes make it difficult to compare results across studies. It is important to consider functional outcomes that are meaningful to athletes/patients such as a return to their preinjury levels of function and performance.\(^{38}\) Thus, we recommend that clinical evaluation and future research include three components in the determination of recovery:

1. **Assessment of symptom reports** (including concussion-related symptom resolution at rest, with cognitive activities and following physical exertion).
2. **Other outcomes relevant to ongoing symptoms or a specific research question** (eg, response to physical exertion, post-traumatic headaches, standing balance, dynamic balance, vestibulo-ocular reflex (VOR) function, oculomotor (OM) function, symptom reproduction with VOR and OM testing (eg, VOMS), cognition, dual tasking).
3. **Measures of return to activity such as RTL and RTS** (see below).

**Role of biomarkers and technology in assessing recovery**

Advanced neuroimaging, fluid-based biomarkers, genetic testing and other emerging technologies are useful for research focused on SRC diagnosis, prognosis, and recovery. However, further research is required to validate their use in clinical practice to assess recovery and aid in the clinical management of SRC.\(^{39}\)

In the research setting, the employment of advanced neuroimaging, fluid-based biomarkers, electrophysiological measures and modalities assessing autonomic dysfunction show promising sensitivity to acute neurobiological effects and changes over the course of SRC recovery. Moreover, evidence across multiple biomarker domains suggests that a time window of physiologival change may extend beyond clinical recovery (ie, resolution of clinical signs and symptoms). However, it remains unknown whether residual alterations are pathological, adaptive or benign processes given insufficient longitudinal data linking neurobiological change to clinical indices of recovery.\(^{39}\)

**RETURN-TO-LEARN AND RETURN-TO-SPORT**

Since the introduction of the RTL and RTS strategies, there has been a fivefold increase in the time to unrestricted RTS.\(^{40}\) Many questions remain about how to optimise RTL and RTS. Importantly, measures used to assess recovery have moved beyond symptoms, cognitive function and balance, to include measures of oculomotor and vestibular function, as well as biobehavioural and physical examination findings (as per SCOT6/Child SCOT6).\(^{25}\) While immediate and early postinjury symptoms remain the most robust predictor of recovery, the emergence of new assessment tools and variability in recovery endpoints underscores the importance of consistent definitions and measurement approaches. The systematic review of RTL and RTS found that continuing to play and delayed access to HCPs after SRC are associated with longer recovery.\(^{41}\) In addition, similar RTL and RTS management strategies can be implemented in different cohorts (eg, age, sex) with minimal differences in the time for recovery.\(^{41}\)

The systematic review revealed wide variability in clinical time points for recovery from SRC, making the integration and interpretation of results from multiple studies challenging, and limiting our ability to develop recommendations applicable to the individual athlete.\(^{41}\) To improve our clinical recommendations, the following definitions have been adopted by the Amsterdam consensus panel:

- **Symptom resolution at rest**: resolution of symptoms associated with the current concussion at rest.
- **Complete symptom resolution**: resolution of symptoms associated with the current concussion at rest with no return of symptoms during or after maximal physical and cognitive exertion.
- **Return-to-learn (RTL)**: return to preinjury learning activities with no new academic support, including school accommodations or learning adjustments.
- **Return-to-sport (RTS)**: completion of the RTS strategy with no symptoms and no clinical findings associated with the current concussion at rest and with maximal physical exertion.\(^{41}\)
RETURN-to-learn (RTL)
The transition back to learning and to school following SRC is an important consideration for children, adolescents and young adults. The systematic review revealed that the vast majority of athletes (93%) of all ages have a full RTL with no additional academic support by 10 days.\(^\text{41}\) While many students can quickly return to learning with no or minimal difficulty, the RTL process can be more challenging for those who have specific considerations (eg, high acute symptom severity, a prior learning disability) that may affect recovery. To minimise academic and social disruptions during the RTL strategy, HCPs should avoid recommending complete rest and isolation, even for the initial 24–48 hours, and instead recommend a period of relative rest. Early return to activities of daily living should be encouraged provided that symptoms are no more than mildly and briefly increased (ie, an increase of no more than 2 points on a 0–10 point scale for less than an hour). In consultation with educators, and accounting for social determinants of health, some students may be offered academic supports to promote RTL including:
- **Environmental adjustments**, such as modified school attendance, frequent rest breaks from cognitive/thinking/desk-work tasks throughout the day and/or limited screen time on electronic devices.
- **Physical adjustments** to avoid any activities at risk of contact, collision or falls, such as contact sports or game play during physical education classes or after-school activities, while allowing for safe non-contact PA (eg, walking).
- **Curriculum adjustments**, such as extra time to complete assignments/homework and/or preprinted class notes.
- **Testing adjustments**, such as delaying tests/quizzes and/or permitting additional time to complete them.\(^\text{41}\)

**Return-to-learn recommendations**
Facilitating RTL (table 1) is a vital part of the recovery process for student-athletes. HCPs should work with stakeholders on education and school policies to facilitate academic support, including accommodations/learning adjustments for students with SRC when needed. Academic support should address factors that may prolong RTL (eg, social determinants of health, higher symptom burden) by adjusting environmental, physical, curricular and testing factors as needed. Not all athletes will need an RTL strategy or academic support. If symptom exacerbation occurs during cognitive activity or screen time, difficulties with reading, concentration or memory or other aspects of learning are reported, clinicians should consider the implementation of an RTL strategy at the time of diagnosis and during the recovery process. When the RTL strategy is implemented, it can begin following an initial period of relative rest (Step 1: 24–48 hours following injury), with an incremental increase in cognitive load (Steps 2–4).\(^\text{41}\) Progression through the strategy is symptom limited (ie, no more than a mild and brief exacerbation of current symptoms related to the current concussion) and its course may vary across individuals based on tolerance and symptom resolution. Further, while the RTL and RTS strategies can occur in parallel, student-athletes should complete full RTL before unrestricted RTS.\(^\text{41}\)

**RETURN-to-sport (RTS)**
Evidence from applied research and improved awareness of SRC have enhanced SRC policies and legislation, removal from play and medical oversight that allows athletes adequate time to achieve recovery before full RTS (table 2). Research is clear that HCPs should avoid prescribing absolute physical and cognitive rest (ie, ‘cocooning’) after SRC; instead, they should allow athletes to engage in activities of daily living (including walking) immediately following injury, even during the initial period of 24–48 hours of relative rest.\(^\text{40,41}\) Light PA as well as prescribed subthreshold aerobic exercise treatment in a safe and supervised environment can be used therapeutically (ie, as part of the treatment plan as outlined in the Rest and Exercise section). Athletes may begin Step 1 (ie, symptom-limited activity) within 24 hours of injury, with progression through each subsequent step typically taking a minimum of 24 hours. Progression through the later RTS strategy (Steps 4–6) should be monitored by an HCP. Incremental progression of the cognitive load on the athlete, using the magnitude of symptom exacerbation as a guide, provides the athlete with the opportunity to increase confidence throughout recovery,\(^\text{42}\) supporting psychological readiness to return to competitive play\(^\text{43,44}\) and fostering a shared RTS decision-making model.\(^\text{44,45}\) Unrestricted RTS following SRC typically occurs within 1 month of injury in children, adolescents and adults, with an estimated pooled mean time to RTS of 19.8 days (95% CI: 18.8 to 20.7 days, n=57 studies, I-squared=99.3%, Q-statistic <0.01).\(^\text{45}\) Providers should manage athletes on an individual basis, accounting for specific factors that may affect their recovery trajectory, such as pre-existing factors (eg, migraine history, anxiety) or postinjury factors (eg, aggravation of injury, psychological stress, social factors) that impact recovery. When symptoms are persisting, worsen or are not progressively resolving 2–4 weeks postinjury, a multimodal evaluation\(^\text{45}\) and referral for rehabilitation (see Rehabilitation section) is recommended.\(^\text{45}\)

<td>Return to school full time</td>
<td>Gradually progress in school activities until a full day can be tolerated without more than mild* symptom exacerbation.</td>
<td>Return to full academic activities and catch up on missed work</td>
</tr>
</tbody>
</table>

*Based on the clinical judgment of the HCP

Following an initial period of relative rest (24–48 hours following an injury at Step 1), athletes can begin a gradual and incremental increase in their cognitive load. Progression through the strategy for students should be slowed when there is more than a mild and brief symptom exacerbation.
Consensus statement

<td>Add movement, change of direction</td>
</tr>
</tbody>
</table>

Steps 4–6 should begin after the resolution of any symptoms, abnormalities in cognitive function and any other clinical findings related to the current concussion, including with and after physical exertion.

4    | Non-contact training drills | Exercise to high intensity including more challenging training drills (eg, passing drills, multiplayer training) can integrate into a team environment. | Resume usual intensity of exercise, coordination and increased thinking |

5    | Full contact practice | Participate in normal training activities. | Restore confidence and assess functional skills by coaching staff |

6    | Return to sport | Normal game play. | |

*Mild and brief exacerbation of symptoms (ie, an increase of no more than 2 points on a 0–10 point scale for less than an hour when compared with the baseline value reported prior to physical activity). Athletes may begin Step 1 (ie, symptom-limited activity) within 24 hours of injury, with progression through each subsequent step typically taking a minimum of 24 hours. If more than mild exacerbation of symptoms (ie, more than 2 points on a 0–10 scale) occurs during Steps 1–3, the athlete should stop and attempt to exercise the next day. Athletes experiencing concussion-related symptoms during Steps 4–6 should return to Step 3 to establish full resolution of symptoms with exertion before engaging in at-risk activities. Written determination of readiness to RTS should be provided by an HCP before unrestricted RTS as directed by local laws and/or sporting regulations. RTC, return to contact; SRC, return to sport; maxHR, predicted maximal heart rate according to age (ie, 220-age).

RTS (see RTL strategy) and under the supervision of a qualified HCP. Following an initial period of relative rest (Step 1: approximately 24–48 hours following injury), clinicians can implement Step 2 (ie, light (Step 2A) and then moderate (Step 2B) aerobic activity) of the RTS strategy as a treatment of acute concussion. 10 41 The athlete may then advance to Steps 3–6 on a time course dictated by symptoms, cognitive function, examination findings and clinical judgement. Differentiating early activity (Step 1), aerobic exercise (Step 2) and individual sport-specific exercise (Step 3) as part of the treatment of SRC from the remainder of the RTS progression (Steps 4–6) can be useful for the athlete and their support network (eg, parents, coaches, administrators and agents). Athletes may be moved into the later stages that involve risk of head impact (typically Steps 4–6 and Step 3 if there is any inadvertent risk of head impact with sport-specific activity) of the RTS strategy following authorisation by an HCP and after full resolution of concussion-related symptoms, abnormalities in cognitive function and clinical findings related to the current concussion, including the absence of symptoms with and after physical exertion. Each step typically takes at least 24 hours. Clinicians and athletes can expect a minimum of 1 week to complete the full rehabilitation strategy, but typical unrestricted RTS can take up to 1 month post-SRC. The time frame for RTS may vary based on individual characteristics, necessitating an individualised approach to clinical management. Athletes having difficulty progressing through the RTS strategy or with symptoms and signs that are not progressively recovering beyond the first 2–4 weeks may benefit from rehabilitation in addition to the RTL and RTS strategies38 (see Rehabilitation section) and/or involvement of a multidisciplinary team of HCPs experienced in managing SRC (see Refer section).37 Medical determination of readiness to return to at-risk activities should occur prior to returning to any activities at risk of contact, collision or fall (eg, multiplayer training drills), which may be required prior to any of Steps 4–6, depending on the nature of the sport or activity that the athlete is returning to and in keeping with local laws/requirements.

### RECONSIDER: POTENTIAL LONG-TERM EFFECTS

There is increasing societal concern about possible problems with later-in-life brain health in former athletes, such as mental health problems, cognitive impairment and neurological diseases. The literature was reviewed for published studies using research designs that could estimate future risk to former athletes (ie, cohort studies and case–control studies). These research designs, either prospective or retrospective, require that an exposed and an unexposed group be followed through time to the outcome of interest.49

Studies that examined mental health as an outcome found that (1) former amateur athletes (primarily American football players) are not at increased risk for depression or suicidality during early adulthood or as older adults,50–54 (2) former professional soccer players are not at increased risk for psychiatric hospitalisation during their adult life55 and (3) former professional football and soccer players are not at increased risk for death associated with a psychiatric disorder55–59 or as a result of suicide.55–59

Other studies evaluated cognitive impairment, neurological disorders (eg, dementia) and neurodegenerative diseases (eg, Alzheimer’s disease, Parkinson’s disease and amyotrophic lateral sclerosis (ALS)) as the outcome. Former male amateur athletes were not at increased risk for cognitive impairment, neurological disorders or neurodegenerative diseases compared with men from the general population.53 60–62 In contrast, studies of former professional athletes examining causes of death reported greater morality rates from neurological diseases and dementia in former professional American football players63–65 and professional soccer players.66 Former professional football players64 65 and soccer players19 66 67 have greater mortality rates from ALS. ALS is a rare disease with a possible genetic cause in some cases of men who develop the disease before age 50,68 and it involves a
highly selective population of neurons, about half of which are in the spinal cord, which makes identifying specific trauma-related aetiological mechanisms challenging.

The studies, to date, are methodologically limited because most were not able to examine, or adjust for, many factors that can be associated with the mental health and neurological outcomes of interest. The studies examining cognitive impairment and neurological outcomes did not examine genetic factors and usually did not consider or control for factors known to be important for brain health in the general population, such as educational attainment, socioeconomic status, smoking, hypertension and cardiovascular disease, diabetes, sleep apnea, white matter hyper-intensities, social isolation, diet, PA or exercise. To establish a clear causal association between sports participation early in life and cognitive impairment or dementia late in life or to quantify that association, future well-designed case-control and cohort studies, that include as many individual risk-modifying and confounding factors as possible, are needed.

Chronic traumatic encephalopathy-neuropathological change and traumatic encephalopathy syndrome

Historically, a clinical condition associated with chronic traumatic brain injury in boxers was described using terms like punch drunk, dementia pugilistica and chronic traumatic encephalopathy (CTE). In recent years, CTE has been described as a neuropathological entity. To avoid conceptual confusion between the pathology and a possible clinical condition, the post-mortem neuropathology is referred to as CTE neuropathologic change (CTE-NC). The literature suggests that CTE-NC is very uncommon in community samples and brain banks, using strict criteria for case identification, and more common in brain bank samples of former professional athletes with high exposure to repetitive head impacts. However, these studies of former athletes are not cohort studies that can examine causation or quantify risk and thus were not included in the systematic review. It is reasonable to consider extensive exposure to repetitive head impacts, such as that experienced by some professional athletes, as potentially associated with the development of the specific neuropathology described as CTE-NC.

CTE-NC is not a clinical diagnosis. The first consensus criteria for traumatic encephalopathy syndrome (TES), a new clinical diagnosis, were published in 2021. These diagnostic criteria can be used to determine the extent to which CTE-NC identified after death was associated with this new clinical diagnosis during life. The prevalence of CTE-NC (a neuropathological entity) and TES (a clinical diagnosis) in former athletes, military veterans and people from the general population is not known. It is also not known whether (1) CTE-NC causes specific neurological or psychiatric problems, (2) the extent to which CTE-NC can be clearly identified within the presence of Alzheimer’s disease neuropathology or (3) whether CTE-NC is inevitably progressive.

RETFINE

There is no clear evidence of the factors that, if present, would unequivocally lead to retirement or discontinued participation in contact or collision sports. However, some sports have their own specific medical regulations regarding clearance for participation (e.g., retinal detachment in boxing).

Decisions regarding retirement or discontinuation from contact or collision sports are complex and multifaceted and should involve clinicians with expertise in traumatic brain injury and sport and preferably a multidisciplinary team. The decision-making process should include a comprehensive clinical evaluation that considers the following factors: injury characteristics; TBI history; cognitive/behavioral symptoms; return to play, the process of recovery and return to sport; previous injury experience and disability status; and the athlete’s preferences and risk tolerance as well as psychological readiness to make an informed decision. The discussion should be carefully documented and should use language that is appropriate for the health literacy of the individual to reduce the risk that the information is misinterpreted. For children and adolescents, the parent/guardian should be involved in the discussion. HCPs should make the athlete aware of the role(s) they are playing in the athlete’s care, stating clearly if they have any potential or actual conflicts of interest. The shared decision-making process should be individualised and incorporate a comprehensive clinical evaluation that may involve a multidisciplinary team and considers patient-, injury-, sport-specific and other sociocultural factors. These principles also apply to all of those involved in the coaching and management of the athlete.

In the child or adolescent athlete, additional concerns are a successful return to school and to maintain healthy levels of PA. This often requires a multidisciplinary process that includes the child/adolescent, parent/caregivers, HCPs, school leadership and teachers in the discussions. Given the positive benefits of exercise on health, care must be taken to avoid restricting all PA. All athletes who ultimately retire from contact or collision sports should be encouraged to continue non-contact or low-contact PA and have the health benefits of exercise explained.

REFINE

Additional topics of relevance to SRC were included in the Amsterdam consensus. Several considerations that could strengthen the consensus process were identified and are described below.

Para sport

Participation in sport across the lifespan for people with disabilities, estimated at 15%–25% of the global population, is increasing. Modern definitions of disability are broad-ranging and inclusive of impairment types that span the Paralympic movement (eg, physical disability, blind/low vision, intellectual disability), Special Olympics (eg, intellectual disability, developmental disability) and Deaflympics (eg, deaf, hard of hearing). Many people with disabilities also participate, train and compete in mainstream sporting environments.

The concussion experience of the para athlete is unique, due to the interaction of the individual’s primary impairment and the pathophysiology of concussion. Para athletes may experience a concussion in widely played sports like ice hockey and soccer, as well as in para-athlete-specific sports such as wheelchair racing and para swimming. Commonly used SRC tools (eg, SCAT) are not validated in the para athlete population, who require a more individualised approach.

Although the literature describing SRC in people with disabilities is limited, elite Paralympic athletes are known to be at higher risk of injury when compared with athletes with no disability. Additionally, athletes with visual impairment may be at even greater risk of concussion, as the mechanisms of injury in this population are primarily through collisions or direct head contact. Moreover, it is likely that prevention approaches, detection of initial symptoms, diagnosis, recovery (ie, potential for persisting symptoms of concussion) and treatment strategies...
may be impacted by the characteristics of the individual’s underlying impairment.

The recent position statement of the Concussion in Para Sport Group summarised expert opinion regarding concussion prevention, assessment and management in para sport participants. Most significantly, (1) individuals may benefit from baseline testing given the variable nature of their disability and the potential for atypical presenting signs/symptoms of concussion, (2) individuals with a history of central nervous system injury (eg, cerebral palsy, stroke) may require an extended period of initial rest, (3) testing for symptoms of concussion through recovery may require modification such as the use of arm ergometry as opposed to a treadmill/stationary bike and (4) RTS protocols must be tailored and include the use of the individual’s personal adaptive equipment and, for applicable participants with visual impairment, partnership with their guide.

Future research is needed to enhance our knowledge of concussion assessment and management in para sport participants. This should include longitudinal injury surveillance to examine modifiable risk factors and prevention strategies, establishing reference data for commonly used assessment tools, evaluating outcomes of concussion and the intersection of the individual’s primary impairment type and understanding the unique challenges of under-researched subpopulations such as the female and child/adolescent with a disability.

Paediatrics
Brain development in the child (5–12 years) and adolescent (13–18 years) and the requirement for return to school guidance necessitate modified paradigms in paediatric SRC. Prevention efforts are important, and rule changes and contact practice limitations for children and adolescents participating in ice hockey and American football have demonstrated reduced SRC incidence rates. The application of such rules in other sports requires more research. The benefits of mouthguards in children and adolescent ice hockey are clear and should be evaluated across all collision sports. NMT warm-up programmes are recommended in rugby with more research needed in female athletes and other team sports. Further research evaluating headgear in non-helmeted sports is required to inform recommendations.

Paediatric athletes are less likely to have trained medical personnel available on the sideline, and it is strongly recommended that the CRT6 be used by all adults supervising child and adolescent sport. The Child SCAT6 (8–12 years) and SCAT6 (adolescents) should be used by HCPs; however, baseline testing is of limited use in younger athletes because of neurocognitive development. Evaluation with the Child SCAT6/SCAT6 provides a framework for multiple domain assessments and informs the clinician on implementing appropriate exercise, RTL and RTS, and rehabilitation. Such a multifaceted clinical evaluation is recommended to guide both management and the possible need for referral to practitioners from multiple disciplines experienced in paediatric SRC.

Return-to-school is a priority in children and adolescents, and while full RTL is recommended before unrestricted RTS, the two strategies can occur in parallel. The use of advanced neuroimaging, fluid biomarkers and other technologies is under investigation for SRC diagnosis, prognosis and recovery; however, age-specific data are required to accommodate physiological and neurocognitive development in the child athlete.

Children and adolescents with repeat concussions wishing to continue to play or to progress to the next age-level group or elite pathway programmes require individualised assessment. Considering the health benefits of a physically active lifestyle, any child/adolescent advised against participating in contact sport should be encouraged to participate in other non-contact sporting or exercise activities.

The athlete’s voice
The Scientific Committee deemed it important to include the athlete’s perspective in this consensus process. There was athlete representation (both in-person and via prerecorded videos) at the conference but not on the subsequent scientific expert panel. Although none of these athletes had direct input into the consensus statement itself, the experience that they shared at the conference around the topics of concussion diagnosis, retirement due to concussion, concussion in youth sport, readiness to RTS following concussion, concussion in para athletes and prevention of concussion provided valuable first-person perspectives for the expert panel.

Ethical considerations, limitations and improvements
While many advances have been made, we recognise that future consensus processes should evolve and strive to improve areas that integrate principles of modern ethics, process, methodology and healthcare practice. These include the five topics discussed below.

Equity, diversity and inclusion (EDI)
Historically, the expert panel of researchers and clinicians was selected on the basis of specific expertise but had limited demographic (eg, gender, race/ethnicity) and geographical (eg, country and continent of origin, low- and middle-income countries) diversity. The benefits of gender and ethnic diversity in advancing science and innovation are well described. Although the Amsterdam Scientific Committee and expert panel were the most diverse to date in the concussion in sport consensus process, significant deficiencies and challenges remain in achieving greater inclusivity regarding demographic and geographical diversity. Addressing this will add diverse perspectives to broaden research, knowledge translation and clinical practice into the assessment and management of SRC globally.

Stakeholder voices
Beside including the athlete’s voice, future consideration could be given to a more integrated codesign with stakeholder participation including parents, teachers, officials, coaches and sports administrators. Comments from the conference participants were also scribed, many of which included stakeholder voices expressing their perspectives and insights as youth athletes, para athletes, professional athletes, family members, sport policymakers and others.

Observer input
The expert panel session benefited from the presence of several observers experienced in the field of SRC. Many of these observers shared their input as co-authors on the systematic reviews, while others were able to provide comment during the public open forums at the conference. Consideration could be given to more formally documenting their appointment, allowing further expert input and including their input into the consensus process.
Sustainability of the consensus process
The exponential increase in SRC scientific publications has greatly amplified the workload on the authors involved in the preparation of the systematic reviews. Consideration could be given to the creation of teams of dedicated clinicians and scientists assigned to narrower topics and questions, or perhaps the development of ‘living’ or regularly updated systematic reviews where new data productions and scientific advancements are rapid.

Potential conflicts of interest and transparency
Considerable efforts were made to record potential conflicts of interest among the members of the leadership group, contributors to the systematic reviews, expert panels and commentators from the floor at the consensus meeting. All speakers declared their interests at the beginning of their presentations (which were recorded on a digital repository), and all contributors from the floor of the consensus meeting were required to do the same verbally. This greater transparency enabled a critical appreciation of the context from which questions, challenges and criticisms were made.

Timing of the consensus meeting and expert panel consensus meeting
All 10 systematic reviews (SRs) were read by the expert panel in advance of the meeting but were then not yet in their final published form. To ensure that the outputs of the consensus were aligned with the final SRs accepted for publication, the lead authors of the SRs as well as of the Consensus Statement cross-checked the recommendations. The final consensus statement was not submitted in its final revised form until the completion of this additional step of the process to ensure that the Consensus Statement aligned with the final SR recommendations.

FUTURE RESEARCH
As part of their task, each author group identified gaps in the research. These gaps included additional topic areas of research, other geographical locations (ie, outside of North America), cultural contexts and ages, sexes and genders, which are described in each systematic review. The audience was also invited to share priorities for future research. A total of 342 participants responded to prioritise their top five topics for research, with potential long-term effects ranking first and prevention ranking second (figure 3).

Figure 3 Percentage of conference attendees who voted for each topic as a top five priority for future research.

Potential long-term sequelae
The potential long-term mental health and neurodegenerative effects of concussion and repetitive head impacts are of increasing interest in the field and have dominated the public discourse on the possible long-lasting effects of collision/contact sports participation. This consensus process has revealed a spectrum of perspectives and the complexities of answering these important questions to which they give rise. Defining the methodology for adequate study designs to better understand if there is a link between neuropathological findings and in vivo processes should be prioritised. The ethical and scientific challenges related to the issue of potential long-term effects of concussion require an ongoing and collaborative process. The Scientific Committee proposes the formation of an interdisciplinary working group, including members of CISG, as well as other clinicians, scholars and scientists, to continue deliberations on these topics in the interest of athlete care. As part of their charge, we recommend this group seek dedicated funding for research into long-term athlete health and consider a separate conference to afford greater time and attention to this topic.

CONCLUSIONS
The 6th International Conference on Concussion in Sport (Amsterdam 2022) was the culmination of a 5-year process resulting in the development of this Statement and the accompanying sports concussion assessment tools. This consensus process took 2 years longer than initially planned due to pandemic-related postponements and aimed to be more extensive than previous versions. This Statement summarises the state of the science, incorporates several novel aspects and has identified priorities for research. The conference outcomes are intended to serve as summaries of the evidence at the time of the Amsterdam Conference to inform HCPs and sports organisations in the interests of improving athlete care at all levels of sport.

JSP and KJS co-reviewed and approved the final manuscript for submission. JSP and KJS co-authored the initial version of this article. The authors would like to acknowledge those colleagues who acted as chairs at the 6th International Conference on Concussion in Sport: Paul Ellason, Christy Fehr, Colm Fuller, Emily Heming, Kirsten Holte, Benjamin Leggett, Linden Penner, Heather A Shepherd, Isla J Shill, Stacy Sick and Stephen W West. In addition, we thank the librarians who assisted with the searches for the systematic reviews, K A I I x H a y d e n and Zahra Premji.

This work was completed as part of the 6th International Consensus on Concussion in Sport. The Scientific Committee included KE, JP, ID, OHA, CAB, RCC, GAD, RIE, MM, MJM. This work was supported by the conference organizing committee which included an educational grant and conference logistic support from the funding partners of the Organizing Committee: International Olympic Committee (IOC), Fédération Internationale de Football Association (FIFA) International Ice Hockey Federation (IIHF), Fédération Equestre Internationale (FEI), World Rugby and the Fédération Internationale de l’Équitation (FIE).

All authors participated as expert panelists for the Amsterdam International Consensus on Concussion in Sport. Authors participated in the expert panel meetings, reviewed the submitted version of the systematic reviews, methodology paper and tools that were submitted to BJSM and reviewed and approved the final manuscript for submission. JSP and KJS co-chaired the process and drafted the consensus statement.

The conference organization and administrative portions of the process were funded by the Organizing Committee for the Sixth International Conference on Concussion in Sport.

GH is a Senior Physiotherapist at University Hospitals Dorset NHS Foundation Trust (England) and is a Football Physiotherapist for Bournemouth and Poole Football Club (salaried). He has a paid consultant role with the Football Association as the squad physiotherapist to the England National Team. He also serves on the British Association of Sports and Exercise Sciences Ethics Committee and the Football Association’s Advisory Board for the Prevention of Concussion in Sport as well as on the International Paralympic Committee (IPC) Medical and Scientific Committee (unpaid) and the IOC Medical and Scientific Committee (unpaid). He is also an Institutional Ethics Committee external member for World Rugby (unpaid) and co-chair of the Concussion in Para Sport Group (unpaid) and the International Federation of Cerebral Palsy Football as Medical and Sports Science Director (unpaid) and the International Blind Sports Federation as Concussion Scientific Committee; Section Editor, Sport and Rehabilitation, Neurosurgery and has attended meetings organised by sport organisations including NFL, NRL, IHF, IOC and FIFA; however, he has not received any payment, research funding or other monies from these groups other than for travel costs. GH is a Football Physiotherapist for Bournemouth and Poole Football Club and an external peer-reviewer for The British Journal of Sports Medicine (BJSM). He has no conflicts of interest.

JSP is a Professor of Sports Neuroscience at the University of Washington. DCJ is the Director of Sports Neurology at the University of California, San Francisco. JSP and KJS are both consultants to the NFL and the NFL Player’s Association as research partners for Injury Prevention and Control Board Pediatric Mild Traumatic Brain Injury (PTBI) research. He has also served as a consultant on the NFL/Under Armour/GE patient outcome study. JSP is a consultant to the NFL SHRED Concussions external advisory board (unpaid). He is the Medical Director of the NFL National Medical and Scientific Advisory Committee (MASC) and has attended meetings organised by sport organisations including NFL, NRU, IHF, IOC and FIFA; however, he has not received any payment, research funding or other monies from these groups other than for travel costs. JSP has served on the Board of Directors of the US Olympic & Paralympic Committee (unpaid) and is the Medical Director of the NFL SHRED Concussions external advisory board (unpaid) and the IOC Medical & Scientific Committee (unpaid). He is an Associate Editor of the British Journal of Sports Medicine (unpaid) and the PM&R Journal (unpaid). He is also a member of the International Paralympic Committee’s Medical and Scientific Committee (unpaid) and the IOC Medical & Scientific Committee (unpaid). He is an Associate Editor of the British Journal of Sports Medicine (unpaid) and the PM&R Journal (unpaid). He has received no travel or accommodation support for meetings where he has presented. JSP is also a consultant to the NFL as a consultant to the NFL’s concussion committee and has received research funding from the NFL’s concussion committee (unpaid). He has no other conflicts of interest.

KJS is the Director of the Concussion Program at the Neurosurgery Section, School of Medicine, University of Washington, Seattle, Washington, USA. He is also an Institutional Ethics Committee external member for World Rugby (unpaid) and the IOC Medical and Scientific Committee (unpaid), NFL Play Smart Play Safe Program and World Rugby. He is also a member of the International Paralympic Committee’s Medical and Scientific Committee and the International Olympic Committee’s Medical and Scientific Commission (IOC) and has served as the Scientific Director of the Concussion in Sport Group (CISG) for talks held on the 20th Anniversary of the Concussion in Sport Group (CISG). He is also an Institutional Ethics Committee external member for World Rugby (unpaid) and the IOC Medical and Scientific Committee (unpaid). He is an Associate Editor of the British Journal of Sports Medicine (unpaid) and the PM&R Journal (unpaid). He has received no travel or accommodation support for meetings where he has presented. JSP is also a consultant to the NFL as a consultant to the NFL’s concussion committee and has received research funding from the NFL’s concussion committee (unpaid). He has no other conflicts of interest.
